digoxin, a putative ABCB1 substrate exhibiting good bioavailability [121,122]. Like CYP3A4 substrates, if low bioavailability is a necessary precondition for the development of clinically relevant GFJ-ABCB1 transporter interactions, digoxin may not be an ideal candidate from which to draw conclusions. Because many drugs affected by GFJ are dual substrates for CYP3A4 and ABCB1 (e.g., cyclosporine, simvastatin, and lovastatin), it appears that the brunt of GFJ's effect is borne by CYP3A4. Citrus juices can, however, inhibit the function but not expression of human intestinal uptake transporters like the solute carrier organic anion transporter family member 1A2 (SLCO1A2), which appears to be particularly affected [123,124]. The oral bioavailability of fexofenadine and cefiprolol, two substrates of human SLCO1A2, are substantially reduced in the presence of GFJ and orange juice [125–128]. It appears that citrus flavonoids (e.g., naringin and hesperidin), and not furanocoumarins, propagate the SLCO1A2 inhibitory effects of these fruits [129]. Even noncitrus juices (e.g., apple) have been recognized for their ability to reduce SLCO1A2 substrate bioavailability [126].

In summary, unique PSMs found in citrus fruits used by millions of people daily can, in normal servings, markedly affect human drug disposition. Given their phytochemical complexity, it is likely that an array of PSMs (e.g., furanocoumarins, flavonoids, and others) working in concert—perhaps synergistically—contributes to the varied effects fruit juices have on drug absorption [130].

Interaction risk: High.

16.6 DSHEA, DIETARY SUPPLEMENTS, AND THE RISK FOR HERB–DRUG INTERACTIONS

Botanicals have been the archetype for medicines since ancient times, and still today they serve as sources for modern drug discovery. While their use in contemporary American medicine has all but disappeared, they still underpin the philosophies of TCM, Ayurvedic medicine (India), and Kampo medicine (Japan). Up until the early twentieth century, monographs for botanicals and botanical extracts composed a significant part of the United States Dispensatory and the US Pharmacopeia, but the coming of the modern drug industry supplanted their use, relegating them to relative obscurity. That is until 1994, when the United States Congress passed the Dietary Supplement Health and Education Act (DSHEA), legislation that characterized botanical extracts as dietary supplements [131]. A dietary supplement, as defined by the act, is “a product (other than tobacco) added to the total diet that contains at least one of the following ingredients: a vitamin, mineral, herb or botanical, amino acid, metabolite, extract, or combination of any ingredient described previously.”

Often formulated as tablets and capsules, they are sold alongside conventional over-the-counter (OTC) medications in retail outlets; and while not intended to treat, cure, mitigate, or prevent any disease, many consumers view dietary supplements as substitutes for conventional medications [132]. Since their introduction in 1994, dietary supplements have gained a significant foothold in the American health care system. As testament to their popularity, 18% of US adults regularly consume botanical supplements, spending more than \$14 billion annually [133,134]. Current surveys indicate that 20–30% of prescription drug users take medications concomitantly with herbal supplements, oftentimes without notifying their physician or other health care professional [135,136]. Moreover, 70% of regular users of botanical supplements also take prescription medications [135]. Prospects for herb–drug interactions, therefore, are considerable.

Most vulnerable to these types of interactions are the elderly. Adults aged 65 years or older are the greatest consumers of prescription medications, and concurrent use of multiple medications (polypharmacy) is common in this population [137]. When coupled with age-related changes in drug disposition—a normal consequence of growing older—polypharmacy predisposes the aged to adverse drug reactions as well as drug–drug interactions. Over the last five years in the United States, a noticeable increase in botanical supplement usage has occurred among seniors [136,138], with as many as 40–70% of survey respondents reporting regular use of herbal products [136,139,140]. Surveys also indicate that <50% of Americans over age 65 disclose their herbal supplement use to physicians [139,141,142]. This combination of polypharmacy, botanical supplementation, and reticence places the elderly at an increased risk of herb–drug interactions.

16.7 UNCERTAINTY IN PREDICTING AND INTERPRETING HERB–DRUG INTERACTIONS

The molecular mechanism(s) underlying most herb–drug interactions and the clinical magnitude of their effects are oftentimes difficult to discern. The vagaries of these processes are rooted in both plant and human physiology. Factors influencing whether herb–drug interactions are of clinical concern include variable enteric CYP3A/ABC content and activity, human pharmacogenetics, phytochemical synergy, irregularities in phytochemical content, and incongruities between *in vitro* predictions and *in vivo* realities. Other confounders unrelated to physiological issues involve adulteration or contamination of botanicals with prescription medications or other toxins. As seen throughout the remainder of this chapter, inconsistent findings among clinical herb–drug interaction studies are quite common.

16.7.1 Variability in Enteric CYP3A/ABC Content/Activity

CYP3A4 catalyzes the biotransformation of more drugs than any other CYP isoform. Highly expressed in the liver and small intestine, it is a major determinant of drug bioavailability. ABC efflux transporters, localized on the apical surface of intestinal enterocytes, work in concert with CYP3A to regulate drug absorption. Intestinal CYP3A and ABCB1 expression can be extremely variable, with baseline enteric content/activity differing among individuals by as much as 8- and 10-fold, respectively

[143,144]. Intersubject variability in protein expression is also evident for an assortment of SLC transporters as well [145]. Such large interindividual variabilities can have profound effects on drug pharmacokinetic profiles and must be taken into consideration when interpreting clinical herb–drug interaction studies, especially those involving CYP3A4/ABCB1 substrates.

16.7.2 Human Pharmacogenetics

Pharmacogenetics—the study of genetic variation on human drug response—is gaining attention for its impact on the outcome of herb–drug interaction studies [146]. As discussed earlier, certain genetic polymorphisms of human XMEs and transporters may have evolved in response to selection pressures of diets rich in certain plant PSMs [51,52,54]. Individuals expressing mutant XME or transporter alleles, therefore, may respond to the modulatory effects of PSMs differently than subjects homozygous for the wild-type allele. Ginkgo (*Ginkgo biloba*), Baikal skullcap (*Scutellaria baicalensis*), garlic (*Allium sativum*), and milk thistle (*Silybum marianum*) are examples of botanicals whose effects on drug disposition appear to correlate with allelic variants. In a cohort of Chinese volunteers, *G. biloba* supplementation significantly enhanced omeprazole hydroxylation in a CYP2C19 genotype-dependent manner [147]. For those subjects exhibiting a poor metabolizer CYP2C19 phenotype, ginkgo-mediated induction was more pronounced. Similarly, baicalin, a flavone glucuronide isolated from Baikal skullcap, reduced plasma concentrations of rosuvastatin in an SLCO1B1 haplotype-dependent manner [148]. Allicin, an active ingredient in garlic, increased omeprazole AUC in a genotype-dependent manner for homozygous *CYP2C19*1* and heterozygous *CYP2C19*1/*2* carriers, but subjects homozygous for *CYP2C19*2* were not affected [149]. An increase in losartan AUC was also noted for volunteers with the *CYP2C9*1/*1* genotype, but not in *CYP2C9*1/*3* carriers when milk thistle (*S. marianum*) flavanolignans (e.g., silymarin, 140 mg) were administered thrice daily for 14 days [150]. From the preceding examples, it is clear that certain herb–drug interactions may be genotype dependent.

16.7.3 Phytochemical Synergy

Pharmacologic synergy is believed central to PSM defense mechanisms [151,152]. In combating enemies, particularly those having evolved resistance to a specific PSM, plants often utilize multiple phytochemicals whose total effect is greater than the sum of their individual actions. It is believed that phytochemical synergy also underpins the health benefits of fruits, vegetables, and medicinal plants [151,152], and likely orchestrates the interplay among XMEs and transporters when plant-based foods and drugs interact. This purported synergy may involve protection of an active substance from degradation by enzymes; it may facilitate transport across membrane barriers by overcoming multidrug resistance mechanisms; it may improve the aqueous solubility of lipophilic compounds, or involve a combination of measures. Numerous *in vitro* studies reveal an abundance of botanical extracts and purified phytochemicals capable of modulating XME and transporter activity [153–189]. Considering the wide array of PSMs to which intestinal enterocytes are subjected, synergy among components, or at least additivity, may explain the enhanced effects botanicals often exhibit relative to purified phytochemicals [172]. As an illustration of phytochemical pharmacodynamic

synergy, investigators recently demonstrated that the antidepressant properties of SJW extracts hinged on the joint activities of several structurally unrelated PSMs (e.g., hypericins, flavonol glycosides, and hyperforins) [190]. This pharmacodynamic synergy appeared linked to an assemblage of “coeffector” phytochemicals (e.g., procyanidin dimmers, procyanidin trimers, and polyphenols) whose combined effects at improving the solubility and transport of hypericin, a highly lipophilic naphodianthrone, produced a pharmacokinetic synergy [190].

Simply put, when plant foods or extracts are ingested along with highly purified, single-ingredient drug products, cellular defense mechanisms may be overwhelmed by a plethora of chemically diverse PSMs working in concert to affect drug uptake and disposition. Oftentimes, the winner of these isolated “battles” in the “war” between plants and animals will dictate the clinical magnitude of an herb–drug interaction.

16.7.4 Phytochemical Content Variability

When comparing results of clinical herb–drug interaction studies, variability in the phytochemical content of products evaluated is a common confounder. It is not unusual for large variations in phytochemical composition to exist among different brands of the same botanical species and amid batches of the same brand [191–193]. This drawback, often overlooked by clinical scientists, is dependent on the plant species utilized (e.g., *Echinacea purpurea* vs *Echinacea pallida*), country of origin, production practices (e.g., cultivation vs collection), climatic conditions, time of harvest, postharvest storage conditions, plant part utilized (e.g., fruit, leaves, stem, and root), extraction procedure (e.g., aqueous vs nonaqueous solvent extraction), and extract dosage form (e.g., powder, tablet, capsule, and liquid) in creating the final product. Variations in phytochemical type and content are perhaps more important to the safety and efficacy of botanical dietary supplements than for plant-based foods [194]. Unlike fruits and vegetables, where phytochemical exposure is dependent on the quantity ingested, exposure to PSMs in herbal products is dependent on the dose and type of preparation ingested. Botanical products come in a number of different dosage forms including teas (for aqueous extracts), tinctures (alcohol extracts), and capsules and tablets of extracts (aqueous, ethanolic, CO₂, or other extraction solvents). Among extracts, the type of solvent used will determine the PSM profile of a finished product. Many products contain the same relative amounts of PSMs found in the unprocessed herb while others are formulated to contain added levels of “active” compounds. Such concentrated or otherwise modified extracts are more likely to influence XME and/or transporter activity and to produce interactions with concomitantly administered drugs.

Plant extracts are not created equally. Extracts “standardized” to contain known quantities of specific phytochemicals may differ considerably in the content of “non-standardized” components [195,196]. Standardized extracts may also yield dissimilar quantities of PSMs when formulated into various dosage forms by multiple manufacturers [191–193,197]. Dissimilar PSM profiles, in turn, produce disparate effects on XMEs [198]. Variability in manufacturer recommended dose and duration of use are also factors for consideration, not to mention the ingestion of multiple supplements. Moreover, inconsistencies in dosage form performance (e.g., disintegration and dissolution) can also affect the rate and extent at which PSM concentrations reach the intestinal lumen [199]. This is exemplified by an examination of nine separate milk thistle formulations whose 1-h percent release rates of silibinin into an aqueous buffered solution

(pH 7.5, 37°C) ranged from 0% to 85% [200]. Brand-related disparities in phytochemical release rates have been observed for other botanical supplements [201,202]. At present, pharmacopeial recommendations for dissolution tests as a quality control measure for dietary supplements are limited to only a few botanicals [203]. Only recently have good manufacturing practices (GMPs) for dietary supplements been promulgated in the United States [204]; nevertheless, discrepancies in actual phytochemical content versus the stated label claim continue to plague many products [191,205]. Such discrepancies may profoundly affect the interpretations of clinical herb–drug interaction studies, especially, if a botanical supplement’s phytochemical content is not independently verified.

16.8 DISCONNECT BETWEEN *IN VITRO* PREDICTIONS AND *IN VIVO* REALITIES

Most of the published research on herb–drug interactions has focused on *in vitro* evaluations of botanical constituents in microsomal systems, supersomes, expressed enzymes or cell culture systems such as transfected cell lines, primary cultures of human hepatocytes, and tumor-derived cells. As a result, a substantial body of literature—of which only a modest portion is referenced here—indicates that many botanicals and individual phytochemicals appear capable of modulating XME and transporter activity [153–189]. In addition to *in vitro* studies, numerous *in vivo* investigations have been carried out in both animals and humans. Quite often, significant discrepancies exist between *in vitro* predictions and *in vivo* realities. Moreover, the results of animal experiments may not always coincide with clinical findings. Because the study of herb–drug interactions involves a host of complexities, each approach has its advantages and limitations [194,206,207].

16.8.1 *In Vitro* Methods (Advantages and Limitations)

In vitro studies are valuable for evaluating both purified phytochemicals and multicomponent extracts. They can provide mechanistic information about potential interactions, and are relatively simple and inexpensive to perform. Several limitations, however, hamper their utility as predictors of *in vivo* responses [195,206,207]. First, most methods employ solubilizing agents [e.g., dimethylsulfoxide (DMSO), ethanol, and acetonitrile] to facilitate exposure and uptake of poorly water-soluble phytochemicals into cells or microsomes. This practice, however, can exaggerate experimental findings because solubility issues that otherwise limit phytochemical bioaccessibility *in vivo* are circumvented. Second, phytochemical concentrations necessary to modulate enzyme or transporter activity often exceed those achieved *in vivo*. Third, studies examining purified compounds may not reflect the phytochemical complexity typical of extracts that may contribute to the net inhibitory or inductive effects observed. For example, many lipophilic aglycones examined *in vitro* exist as hydrophilic glycosides in extracts, a condition that may limit cellular uptake *in vivo*. Fourth, many PSMs undergo extensive intestinal and/or hepatic metabolism, a condition that may affect their net modulatory effects *in vivo*. Despite these limitations, *in vitro* screening methods can identify botanicals/phytochemicals with inhibitory or inductive potencies that may warrant further examination *in vivo*, even though few significant drug interactions

have actually been discovered or accurately predicted with *in vitro* methods to date [206,207].

16.8.2 *In Vivo* Animal Methods (Advantages and Limitations)

Herb–drug interaction studies conducted in small animals (e.g., mice, rats, and dogs) have advantages of being less expensive than human clinical studies and can often provide an initial assessment of bioavailability either for phytochemicals in pure form or in the context of a complex extract. Limitations of animal studies are that large, nonphysiological doses are often administered and, because of species variation in metabolism and transport, results are rarely generalizable to humans [194,206].

16.8.3 *In Vivo* Human Studies (Advantages and Limitations)

The importance of *in vivo* human studies for investigating herb–drug interactions came to the forefront in 2000 when a succession of clinical case reports revealed that SJW drastically reduced plasma concentrations of the immunosuppressant cyclosporine, precipitating graft rejection in organ transplant recipients [208–210]. Because cyclosporine is a substrate of CYP3A4 and ABCB1, SJW was suspected of inducing the activity of these two important drug disposition proteins. Coincident with the case study series, conflicting *in vitro* studies indicated that SJW either inhibited CYP3A4 [153] or was a potent ligand of the orphan nuclear receptor PXR [211,212]. Only after a series of prospective clinical studies incorporating other CYP3A4 and ABCB1 substrates did it become clear that SJW was indeed a potent inducer of these regulatory proteins [213–217].

Since 2000, substantial numbers of prospective clinical studies incorporating a variety of experimental designs have been conducted (for recent reviews, see Refs 218–228). Typically, subjects receive a single dose of a test drug or a cocktail of drugs that are markers for various enzymes. Individual drug phenotypes (e.g., pharmacokinetic profiles and drug/metabolite ratios) are then determined [68,206]. This is followed by daily multiple dosing of the botanical supplement, usually for 14–30 days, whereupon phenotypic profiling of the test drugs is repeated. A comparison of pre- and post-treatment pharmacokinetic parameters or phenotypic measures is then used to gauge how XME or transporter activities were affected. The principal advantage of this approach is that it offers a definitive means of assessing the magnitude and implications of herb–drug interactions.

Several common oversights, however, can influence the outcome and interpretation of human studies. First, because botanical supplements often exhibit significant brand-to-brand and lot-to-lot variability, commercially available products must be analyzed independently for phytochemical characterization and content. Simply relying on stated label claims is insufficient. Second, disintegration and dissolution characteristics for specific dosage forms should be conducted before study implementation. Dosage forms failing to properly disintegrate or release their purported “marker” compounds within a reasonable time period will preclude any meaningful results. Failure to address these issues makes it difficult to extrapolate from one formulation to another. Third, an assessment of phytochemical bioavailability or detection of marker compounds in circulating plasma or urine provides evidence of exposure as well as subject compliance.

Although desirable, this prerequisite is often limited by the paucity of validated analytical methods available for measuring unique phytochemicals and/or their metabolites in biologic fluids. Furthermore, because of the complexity of botanical extracts, detection of specific marker compounds in biologic fluids may not necessarily establish an individual phytochemical as a causative agent in an observed phenotype change. Fourth, very few studies incorporate positive controls for inhibition (e.g., clarithromycin as CYP3A4/ABCB1 inhibitor) or induction (e.g., rifampin as CYP3A4/ABCB1 inducer) as a means of gauging clinical relevance [229,230]. This last aspect provides a practical framework from which to compare and interpret the clinical relevance of human herb–drug interaction studies.

Recently, the US Food and Drug Administration (FDA) released a set of guidelines for interpreting the clinical significance of drug interactions in the United States [231,232]. These guidelines are based on clinical experience with several well-defined drug interactions, mainly involving the inhibition of CYP3A4. For this interaction mechanism, the benzodiazepine midazolam (MDZ) was shown to be a reproducible probe allowing quantitative determination of the interaction potential of an enzyme inhibitor. For MDZ, the extent of interaction can be measured in the form of an increase in the AUC. The guidelines propose that inhibitors producing changes in MDZ AUC amounting to less than a twofold increase should be classified as “weak.” Increases ranging from two- to fivefold were classified as “moderate,” whereas a strong interaction is marked by increases in MDZ AUC exceeding fivefold. For other CYPs and ABCB1, the guidelines suggest increases in the AUC of specific probes (e.g., warfarin, CYP2C9; omeprazole, CYP2C19; dextromethorphan, CYP2D6; and digoxin, ABCB1) of twofold or higher may constitute clinically significant interactions. Rifampin was identified as an acceptable probe for examining the induction of CYP2B6, CYP2C8, CYP2C9, CYP2C19, CYP3A4, and ABCB1. A reduction in the AUC values of substrates by 30% or greater would constitute a significant induction interaction. For drugs with narrow therapeutic indices, demonstration of a potentially “weak” interaction by a botanical could result in significant adverse side effects. Therefore, for purposes of this review, botanical formulations producing increases in probe drug AUCs of twofold will be classified as “clinically significant” inhibitors, and those reducing probe drug AUCs by 25% or more will be considered “clinically significant” inducers [231,232].

One final limitation of clinical studies is that they can be costly, and it is often difficult to obtain mechanistic information. Nevertheless, clinical studies represent the only reliable means for realistically assessing a botanical supplement’s herb–drug interaction potential [206,207].

16.9 ADULTERANTS AND CONTAMINATION

Dietary supplements have also faced challenges with regard to contamination and adulteration. Contamination with heavy metals, microbial pathogens, pesticide residues, and improperly identified plant material as well as adulteration with toxic plant extracts, pharmaceutical agents, and other inappropriate additives have generated concern among the medical community and lay public [233]. While contamination or adulteration with less noxious substances or botanicals may not be harmful, other additives have been the cause of serious toxicity [233]. Contamination with heavy metals and various toxic herbs is generally more problematic for imported supplements than those produced

domestically [234]. More disconcerting than unintended product contamination has been the seemingly purposeful adulteration of dietary supplements with conventional drugs [235,236]. The FDA has removed a variety of dietary supplements from the market containing undeclared prescription medications and anabolic steroids, several of which have produced toxic manifestations in some consumers [237]. Most supplement manufacturers have avoided this problem through rigorous, proactive implementation of GMPs. Others, however, have been less sedulous in their approach to product quality. Beginning in 2008, the FDA implemented GMPs for supplements, addressing issues with species identification, contamination, and adulteration. Under the GMPs, adulterants continue to be illegal, and testing for certain contaminants is now required. Implementation of these regulations should significantly reduce incidences of adulteration and contamination. Nevertheless, from an herb–drug interaction perspective, effects attributable to botanicals must be differentiated from those produced by adulterants.

16.10 POPULAR DIETARY SUPPLEMENTS AND THEIR DRUG INTERACTION POTENTIAL

What follows are assessments of the available clinical evidence regarding herb–drug interaction potentials for several popular botanical supplements sold in the United States. Following each summary, a probability assessment (low, moderate, or high) will be provided.

16.10.1 Black Cohosh

Actaea racemosa L. (syn. *Cimicifuga racemosa* [L.] Nutt.) or black cohosh, is a perennial herb native to North America used traditionally by Native Americans for female reproductive system ailments and now popular for the relief of menopausal symptoms such as hot flashes [238,239]. The purported ability of black cohosh to help alleviate climacteric symptoms, premenstrual syndrome, and osteoporosis has secured its ranking among the 10 top-selling supplements in the United States [240]. Spiroketal triterpene glycosides (Fig. 16.4) are believed responsible for black cohosh's pharmacological activity even though they are not phytoestrogens [241,242]. As such, most commercial black cohosh products are chemically standardized to triterpene glycosides, with 23-*epi*-26-deoxyacteoin (also known as 27-*deoxyacteoin*) being the most abundant congener [243].

At present, black cohosh does not appear to be a potent modulator of human drug metabolism. *In vitro* studies found individual triterpene glycosides to be relatively weak inhibitors ($IC_{50} > 100 \mu M$) of human CYP3A4 [244,245], while whole extracts elicited greater inhibition, a finding suggestive of synergy [244]. The inhibitory effects of whole black cohosh extracts may stem not from triterpene glycosides but rather fukinolic and cimicifugic acids. These compounds are potent ($IC_{50} < 13 \mu M$) inhibitors of CYP1A2, 2D6, 2C9, and 3A4 *in vitro* [245]; however, their quantities vary considerably among commercially available black cohosh products [246], a factor that can profoundly affect their inhibitory activity *in vivo*. In human liver microsomes, IC_{50} values for CYP2B6, 2C19, and 2E1 were ~ 50 , 30, and $10 \mu g/mL$, respectively for methanolic extracts of black cohosh [189]. However, when compared to standard regimens of clarithromycin (500 mg daily for 7 days) or rifampin (600 mg daily for 7 days)

Figure 16.4 Representative phytochemicals (triterpene glycosides, phenylpropanoids) present in black cohosh.

black cohosh supplementation (40–80 mg extract daily delivering 3–6 mg triterpene glycosides for 14 days) produced no demonstrable effects on MDZ and digoxin pharmacokinetics [229,247]. These findings suggest that black cohosh is not a potent modulator of human CYP3A4 or ABCB1 activity *in vivo*. Black cohosh supplementation also had no clinically significant effects on phenotypic measures of human CYP1A2, 2E1, or 2D6 activity [248]. When administered orally, black cohosh's principal triterpene glycoside, 23-*epi*-26-deoxyacteoin, reaches the systemic circulation intact, albeit in very low concentrations (<10 ng/mL) [243]. This apparent lack of biotransformation bolsters the idea that black cohosh triterpene glycosides are unlikely to be inhibitors of human XMEs *in vivo*. Black cohosh extracts incorporating DMSO as a cosolvent moderately inhibited (~47%) uptake of estrone-3-sulfate, a SLCO2B1 substrate, into human embryonic kidney cells stably expressing the transporter [171]. Whether this effect translates to the *in vivo* condition remains to be determined.

As with most commercially available botanical supplements, black cohosh products exhibit considerable variability in phytochemical profiles, and label claims for “standardized” marker compounds can deviate considerably from actual content [246]. Such variations can have considerable influence on how the results of clinical studies evaluating black cohosh efficacy or its herb–drug interaction potential are interpreted. Nevertheless, based on the currently available data, standardized black cohosh supplements, when taken at recommended doses, pose little risk for herb–drug interactions.

Interaction risk: Low.

16.10.2 Echinacea spp

Echinacea spp. (e.g., *E. purpurea* [L.] Moench, *Echinacea angustifolia* DC., *E. pallida* [Nutt.] Nutt.) of the family Asteraceae are North American perennials, whose roots and aerial parts have been used traditionally for a variety of medicinal purposes [249,250]. *Echinacea* formulations containing either root or whole plant extracts are marketed for their “immune stimulatory” properties and for the prevention of colds [249,250]. *Echinacea*'s popularity as an immune stimulator has placed it among the 10 top-selling botanicals in the United States for many years. While evidence from

in vitro and animal studies lend credence to *Echinacea* preparations as immunomodulators, clinical findings remain equivocal (for reviews of clinical efficacy, see Refs 249–253). The three species most commonly encountered are chemically dissimilar. Both *E. purpurea* and *E. angustifolia* contain alkamides as their major lipophilic constituents, although of differing structural types (Fig. 16.5). By contrast, the lipophilic fraction of *E. pallida* is characterized by polyacetylenes and is practically devoid of alkamides. These phytochemical dissimilarities also extend to their respective plant parts (i.e., roots vs aerial parts). As PSMs, polyacetylenes and alkamides are natural pesticides that, when ingested in relatively high amounts, can be toxic. In low concentrations, however, alkamides appear to have beneficial effects [118]. Other PSMs such as caffeic acid esters (e.g., cichoric acid and echinacoside), polysaccharides, and alkenes are also thought to contribute to echinacea's activity. Because commercially available *Echinacea* supplements often consist of extracts from various species and plant parts, considerable variation in phytochemical profile and content is common among products [250,254].

Permeability [255,256] and pharmacokinetic [257–259] studies indicate that several alkamides, but not caffeic acid conjugates, cross the intestinal mucosa reaching the systemic circulation intact. Following single doses of *Echinacea* alkamides (~11 mg) administered as tablets manufactured from ethanolic liquid extracts, plasma concentrations varied considerably with maximum plasma levels not exceeding 350 ng/mL [259]. Individual *Echinacea* alkamides are metabolized to varying degrees by several human CYPs, but when combined (as in an extract) their metabolism is markedly reduced [260–262]. This appears to arise from

Figure 16.5 Representative phytochemicals (alkamides and phenylpropanoids) present in *Echinacea* spp.

(2*E*)-*N*-isobutylundeca-2-ene-8,10-diynamide (Fig. 16.5), which contains a terminal alkyne and may act as a mechanism-based inhibitor [260]. A considerable number of *in vitro* studies have examined the XME and ABCB1 modulatory effects of echinacea extracts and individual PSMs [154,157,164,169,175,177–180,263–268]. A recent review of the bulk of these studies concluded that alkamides exhibit at least mild to moderate inhibition of CYP3A4 in most of the model systems tested, with the magnitude dependent on alkamide content [262]. This conclusion is strengthened by a recent animal study, in which standardized *E. purpurea* extracts reduced rat CYP3A mRNA levels by 40% [269]. Expression of CYP1A mRNA, however, was increased by 80%. Mild inhibitory effects on ABCB1- [267,268] and SLCO2B1-mediated [171] transport have also been demonstrated.

Very few prospective clinical studies examining the interaction potential of *Echinacea* supplements have been conducted in humans. Using the CYP3A probe MDZ, Gorski *et al.* [270] concluded that eight days of *E. purpurea* supplementation selectively modulated CYP3A activity in the intestine (inhibition) and liver (induction) of healthy volunteers. The authors concluded that because of *Echinacea*'s seemingly opposing effects on intestinal and hepatic CYP3A4, any interaction would depend on the substrate's hepatic and intestinal extraction ratio. Mild inhibitory effects were observed for CYP1A2 and CYP2C9, while CYP2D6 was unaffected. In this instance, however, *Echinacea*'s effect pales in comparison to those reported by these same investigators for known CYP3A4 inhibitors (e.g., clarithromycin) and inducers (rifampin) of MDZ metabolism [271,272]. It would appear that *Echinacea*'s effect on CYP3A expression is modest at best, as neither standardized extracts or purified alkamides upregulated CYP3A4 mRNA levels when exposed to HepG2 cells for 96 h [265]. In contrast, rifampin exposure increased CYP3A4 mRNA expression by 3.8-fold. Using various phenotypic probe drug ratios to assess CYP1A2, CYP2D6, CYP2E1, and CYP3A4 activity, Gurley *et al.* [273] found that healthy adults supplemented with *E. purpurea* for either 14 (800 mg extract daily) or 30 days (1500 mg extract daily) [115] produced no clinically significant changes in CYP phenotypes. More recently, Penzak *et al.* [274] reported that 28 days of *E. purpurea* supplementation in healthy volunteers (500 mg, thrice daily) produced modest reductions in MDZ AUC (27% decrease), but had no significant effects on the pharmacokinetics of lopinavir and ritonavir (CYP3A4 substrates) or fexofenadine (a purported ABCB1 and SLCO substrate). This study, like that of Gorski *et al.*, suggests that *E. purpurea* may have mild inductive effects on human CYP3A4 *in vivo*. However, when compared to rifampin's effects on the pharmacokinetics of CYP3A4 substrates [229,272], any clinically important drug interactions with *Echinacea* seem remote.

To date, only two clinical studies have evaluated *Echinacea*'s impact on drug transporters. Fourteen days of supplementation with a standardized, well-characterized *E. purpurea* product (800 mg extract daily) had no effect on digoxin (an ABCB1 substrate) pharmacokinetics in healthy volunteers [230]. By contrast, seven days of rifampin (600 mg daily) or clarithromycin (500 mg daily) produced marked reductions and increases, respectively in digoxin AUC, a finding that underscores *Echinacea*'s clinically insignificant effect on these transporters. In addition, the pharmacokinetics of fexofenadine, a nonspecific ABCB1 and SLCO substrate, were not impacted by 28 days of *E. purpurea* supplementation [274]. Taken together, these data render it unlikely that *E. purpurea* will produce clinically relevant interactions with coadministered drugs through ABC or SLCO modulation.

On the basis of the collected evidence to date, it appears that dietary supplements formulated with standardized *Echinacea* extracts—when ingested per label recommendations—are not likely to yield alkamide concentrations sufficient enough to dramatically modulate human CYP, ABC, and SLCO isoforms *in vivo*. Therefore, echinacea supplements pose minimal risks for interacting with most conventional medications, an opinion concordant with that of other recent reviews [262,275].

Interaction risk: Low.

16.10.3 Garlic

Members of the family Alliaceae have been an important part of the human diet for thousands of years. *Allium* spp., such as garlic (*Allium sativum* L.) and onions (*Allium cepa* L.) are a rich source of sulfur-containing compounds, many of which are volatile and give rise to the characteristic flavor and aroma of these species. Fresh garlic has little smell but tissue damage by cutting, crushing, or biting results in alliin (2-propenyl-L-cysteine sulfoxide) (Fig. 16.6) being cleaved by the enzyme alliinase resulting in the formation of allicin (diallyl thiosulfinate), which gives crushed garlic its characteristic smell. Because allicin is very unstable to heat, cooking results in its degradation to a number of organosulfur compounds including diallylsulfides and ajoenes [130] (Fig. 16.6). Bad breath, which follows the ingestion of garlic products, is due to a range of sulfide compounds that appear in the systemic circulation and expired air.

Garlic is reputed to have benefits for protection against cardiovascular diseases, cancer, microbial infections, and vampires! Although there is some evidence for the first two effects, the rest are largely the result of speculation and folklore [130]. The putative antihypercholesterolemic effect of garlic supplements makes them one of the most widely used botanical supplements in the United States. Their efficacy, however, remains in doubt because of conflicting results from numerous published clinical trials [276–279]. This is probably a function of the type of product used, its quality, and poor characterization of the phytochemical agent(s) responsible for garlic's lipid lowering effect.

Three general categories of garlic supplements are available commercially: garlic oil, dehydrated garlic powder, and aged garlic extract (AGE), each with their own unique composition of purported bioactive components [280–282]. Within these products a plethora of organosulfur compounds, steroid saponins, and other phytochemicals have been identified [74,280–283]. Of these, the oil-soluble organosulfur compounds including allyl thiosulfonates (e.g., allicin), alkyl sulfides (e.g., diallyl sulfide), vinylthiins, and ajoene have received the most attention (Fig. 16.6). Allicin has long been touted as the agent responsible for garlic's lipid lowering effects, yet the compound is unstable in the gastrointestinal tract, is not bioavailable, and is rarely found in commercial products [280–282]. Allicin's degradation products such as diallyl sulfide, diallyl disulfide, diallyl trisulfide, dithiin, and ajoene may contribute to the lowering of serum cholesterol levels; however, many products, particularly those containing garlic oil, have relatively poor efficacy [284,285]. In addition, many *in vivo* studies indicate that garlic oil and individual alkyl sulfides, most notably diallyl sulfide and allylmethylsulfide, inhibit murine and human CYP2E1 [46,75,286,287]. This is likely a result of the CYP2E1-catalyzed biotransformation of diallyl sulfide to diallyl sulfoxide and diallyl sulfone, in which the latter is a mechanism-based inhibitor of the enzyme [46,288]. Despite

Figure 16.6 Representative phytochemicals (sulfur-containing compounds) present in garlic.

inhibition of human CYP2E1 *in vitro*, few interactions involving garlic products and CYP2E1 substrates have been reported, a consequence that probably reflects the paucity of drugs metabolized by this enzyme. Conversely, prolonged administration of diallyl sulfide and diallyl disulfide induced other hepatic and intestinal murine CYP subfamilies (e.g., CYP1A, CYP2B, and CYP3A), in addition to various transferases (e.g., GSTs and UGTs) [75,289–295] through activation of CAR and Nrf2 nuclear receptors [296].

The ability of garlic to inhibit other human CYP isoforms also appears dependent on product type and composition. *In vitro* assessments of allicin, fresh garlic, or commercially prepared supplements (e.g., garlic oil and garlic powder) either found no effect [164,297] or modest inhibition (<50%) of human CYP2C9, CYP2C19, and CYP3A4 isoforms [155,298]. A freeze-dried garlic supplement, however, produced significant inhibition of CYP3A4 *in vitro* (>95%) [298]. Because the chemistry of garlic

is complex and because different types of processing can significantly alter its phytochemical composition, lyophilization may stabilize those organosulfur compounds capable of inhibiting CYP3A4. AGEs, on the other hand, do not appear to inhibit any of the major CYP isoforms present in human liver microsomes [299]. This may stem from a dearth of oil-soluble organosulfur compounds in AGE and a preponderance of water-soluble components (e.g., *S*-allyl-L-cysteine, saponins) [280]. The shift from oil- to water-soluble ingredients arises from the aging process and subsequent aqueous extraction, which makes AGE distinct from the other types of garlic products.

On the basis of *in vitro* and murine *in vivo* findings, garlic's effects on transporter activity also appear dependent on the hydrophilicity of specific organosulfur compounds. The preponderance of *in vitro* data regarding ABC isoforms implies that garlic's oil-soluble organosulfur compounds are not potent inhibitors of the efflux transporter ABCB1 [95,181,298,300,301], but may, however, induce ABCC2 expression [301]. Interestingly, lipophilic compounds (e.g., diallyl sulfide and diallyl disulfide) increased ABCB1 efflux through rat ileum but not through Caco-2 cell monolayers [302]. When exposed to both Caco-2 cell monolayers and rat intestine at high concentrations ($\sim 12 \mu\text{g/mL}$), water-soluble compounds in AGE (e.g., *S*-allyl-L-cysteine) induced the activity of ABCB1, ABCC2, and SLCO transporters [302,303]. In a HepG2 cell line, however, ABCC2 activity was reduced, suggesting that AGE-mediated regulation of ABCC2 proteins in the liver is different from that in intestine [304]. Tissue-specific regulation of ABCC2 activity has also been observed for other xenobiotics [305], and this may only add to the difficulties of predicting garlic–drug interactions.

A modest number of prospective human studies have investigated the drug interaction potential of garlic supplements or purified garlic organosulfur compounds [48,150,306–316]. Owing to the variety of products evaluated and diverse dosages of garlic phytochemicals administered, results have been mixed. A number of drugs, whose biotransformation pathways run the gamut of human XMEs, have been assessed (e.g., acetaminophen, alprazolam, caffeine, chlorzoxazone, cyclosporine, debrisoquine, docetaxel, dextromethorphan, MDZ, omeprazole, ritonavir, saquinavir, and warfarin), yet the evidence implies that only substrates of CYP2E1 are significantly affected [48,307,313]. The first prospective study by Gwilt *et al.* [306] found that daily administration of AGE ($\sim 19 \text{ mg}$ *S*-allyl-L-cysteine) produced no significant effects on the pharmacokinetics of acetaminophen, a putative CYP2E1 substrate. Later, Loizou and Crocker observed that administration of diallyl sulfide ($\sim 0.2 \text{ mg/kg}$) to healthy volunteers reduced plasma 6-hydroxychlorzoxazone/chlorzoxazone ratios (a phenotypic measure of CYP2E1 activity) by an average of 31% [307]. This finding confirmed in humans what had been previously observed in murine models that lipophilic, and not hydrophilic, organosulfur compounds were CYP2E1 inhibitors. Subsequent studies confirmed that prolonged garlic oil supplementation (500 mg, thrice daily for 28 days) inhibited human CYP2E1 activity in both young [48] and elderly adults [313] by almost 40% and 25%, respectively; however, no modulatory effects were noted for CYP1A2, CYP2D6, or CYP3A4. In contrast, 21 days of twice daily supplementation with garlic powder ($\sim 9 \text{ mg}$ allicin and 23 mg alliin) reduced by 50% the mean AUC, 8-h trough concentrations, and mean maximum plasma concentrations (C_{max}) of the protease inhibitor, saquinavir [308]. The authors concluded that the garlic powder supplement might have induced intestinal CYP3A4 and/or P-gp, since saquinavir is a substrate for both proteins. A similar, although less dramatic, effect on ritonavir AUC, was observed after a four-day course of

garlic extract (5 mg, twice daily) [309]. Subsequent studies examining the prolonged effects of garlic supplementation on other CYP3A4 substrates, however, failed to note any significant changes [310–312]. Also, any clinically important garlic-mediated interactions have not been reported for warfarin, a recognized substrate for CYP2C9 and 3A4 [315,316]. However, large doses of the organosulfur compound allicin (~150 mg daily) did reduce the metabolism of omeprazole by inhibiting CYP2C19 activity in individuals both homozygous and heterozygous for the *CYP2C19*1* allele, but not for those homozygous for *CYP2C19*2* [150]. Interestingly, the CYP3A4-mediated omeprazole sulfone pathway was not affected. The extent to which garlic supplementation affects human ABC and SLCO substrates *in vivo* remains to be determined. Perhaps reductions in saquinavir and ritonavir concentrations noted in early studies could have been attributable to garlic-mediated upregulation of intestinal ABCB1 or ABCC2 activity as was demonstrated in several recent *in vitro* investigations [300–305].

Taken together the accumulated findings imply that most commercially available garlic supplements pose only a limited risk for producing clinically important herb–drug interactions. Presently, only human CYP2E1 appears to be inhibited by garlic oil products, but because only a few drugs are substrates of CYP2E1 and most of those have fairly broad therapeutic indices, this interaction is not a cause for great concern.

Interaction risk: Low.

16.10.4 Ginkgo biloba

Termed a *living fossil*, Ginkgo trees have existed since the early Jurassic period of 150 million years ago. The lone species that escaped extinction (*G. biloba* L.) is now cultivated in Asia, Europe, North America, New Zealand, and Argentina. Ginkgo is a popular ornamental tree recognizable by its unusual fan-shaped leaves that turn bright yellow in autumn. In Asia, the tree has long been held sacred for its therapeutic value. Today, dosage forms incorporating *G. biloba* leaf extracts are used throughout the world for the treatment of insufficient blood flow, memory deficits, cognitive disorders, Alzheimer's disease, depression, vertigo, tinnitus, and intermittent claudication [317]. Ginkgo's popularity has made it one of the most intensely studied botanicals in the world. Currently, more than 2500 articles related to *G. biloba* have been published in the medical literature.

Clinical trials on the efficacy of *G. biloba* extracts are numerous and controversial [318–322]. Much of the research has centered on products formulated with EGb 761, an extract produced by the German company, Schwabe. EGb 761 is a standardized, concentrated extract containing 24% flavonoid glycosides (e.g., quercetin, kaempferol, and isorhamnetin), 6% terpene lactones (3.1% ginkgolides A, B, C, and J and 2.9% bilobalide), 5–10% organic acids, and other constituents [317]. Several other companies produce *Ginkgo* extracts with similar chemical profiles. Terpene lactones are unique to *G. biloba* and include the ginkgolides, a group of diterpene trilactones (e.g., ginkgolide A, B, C, J, and M), and bilobalide, a sesquiterpene lactone (Fig. 16.7). *G. biloba* flavonoids occur principally as glycoside derivatives, with quercetin, kaempferol, and isorhamnetin being the most prevalent. Other PSMs present in *G. biloba* that may have allergenic, immunotoxic, and other undesirable properties (e.g., ginkgetin, amentoflavone, ginkgolic acids, ginkgotoxin, and others) are typically removed during processing [317].

Figure 16.7 Representative phytochemicals (terpene lactones and flavonoid glycosides) present in *Ginkgo biloba*.

Discrepancies among clinical studies regarding efficacy may be traced to significant interproduct variability in phytochemical content and biopharmaceutical characteristics of ginkgo extract dosage forms (e.g., disintegration, dissolution, and bioavailability) [323,324]. These same discrepancies may also underly the confusion surrounding the herb–drug interaction potential of *G. biloba*. Depending on which experimental model is utilized, different interpretations of ginkgo’s drug interaction capabilities emerge. In many *in vitro* experimental systems, ginkgo extracts [152,169,171,174,176,177,180,184,325–329] as well as individual terpene lactones [162,323–329] and flavonoid glycosides [162,171,185,188,325–328,330] have been shown to inhibit various XMEs and transporters, although in most instances IC₅₀ values were well in excess of 20 μM. Aglycones of quercetin, kaempferol, and isorhamnetin seem to have the greatest inhibitory capacity [162,166,185,188,326,329–332], while ginkgolides and bilobalide exhibit the least and, in many cases, none at all [155,166,326–330,333]. In contrast, ginkgo extracts and individual terpene lactones appear capable of inducing the expression of several CYP, UGT, and ABC isoforms in rat [334–336] and human primary hepatocytes [176,184,336,337] as well as human mammary epithelial cells [338]. Cell-based reporter assays in HepG2 [335,337], LS180 [182], and other cell lines [338,339] revealed that ginkgolides A and B are activators of PXR, whereas quercetin and kaempferol activated PXR, CAR, and AhR. Bilobalide exerted no effects on nuclear receptors in these assays. The discovery that specific

ginkgolides and flavonoids are ligands for several xenobiotic receptors provides an explanation for a host of recent *in vivo* studies in which prolonged administration of *G. biloba* extracts to rats, often in high doses, not only induced a multitude of XMEs [340–345] but reduced efficacy for several drug substrates: nicardipine [346], tolbutamide [347], phenobarbital [348], propranolol [349], cyclosporine [350], and theophylline [351]. Concomitant administration of *G. biloba* also enhanced the hepatotoxicity of acetaminophen via CYP3A induction [352]. However, several of these *in vivo* studies contradicted cell-based reporter assay findings when bilobalide was implicated as an XME activator [353–355].

Evidence from *in vitro* and animal investigations clearly points to *G. biloba* extracts and their constituents as inducers of XME and transporter activity. These findings have led investigators to warn of significant drug interactions with *G. biloba*. Clinical evidence substantiating these claims, however, is not as compelling. To date, 29 prospective clinical trials assessing the effect of *G. biloba* supplementation on the pharmacokinetics of a variety of drugs, including several specific CYP probes, have been published [48,147,313,344,356–380]. Twenty-nine different drugs whose metabolism or transport is mediated by various CYP isoforms (e.g., CYP1A2, CYP2B6, CYP2C9, CYP2C19, CYP2D6, CYP2E1, and CYP3A4) or transporters (e.g., ABCB1, SLCO1B1, and SLCO2B1) were evaluated. The drugs included aspirin [371], alprazolam [364], antipyrine [356], bupropion [378], caffeine [48,313,358], chlorzoxazone [48,313,358], cilostazol [366], clopidogrel [366], dapsone [358], debrisoquine [48,313,358], dextromethorphan [361], diazepam [379], diclofenac [367], digoxin [360], donepezil [363], endogenous steroids [344,365], fexofenadine [374], flurbiprofen [368], lopinavir [374], mephenytoin [358], metformin [373], MDZ [48,313,370,374], nifedipine [357,362], omeprazole [147], talinolol [376,377], ticlopidine [369,380], tolbutamide [367,370], voriconazole [375], and warfarin [359,364,372]. The majority of these studies followed a *G. biloba* supplementation regimen of 240 mg leaf extract twice daily from as few as 3 to as many as 90 days, while others utilized smaller doses. In addition, most utilized products containing the standardized EGb 761 extract. Of the 29 studies (many of which evaluated more than one drug), 23 observed no significant effects of *G. biloba* on drug disposition, 5 observed a modest inhibitory effect [357,358,370,376,377], and 3 demonstrated evidence of CYP3A4 [372], CYP2C9 [368], and CYP2C19 [147] induction. Moreover, when compared to FDA guidelines on drug interaction criteria [231,232], those few studies demonstrating a modulatory effect of *G. biloba* on drug disposition do not appear to be clinically important.

Discrepancies in *G. biloba*'s effect on rat and human XMEs *in vivo* do not appear to reflect species differences in PXR activation [335], but rather seem to be dose related [341,344]. Most rat studies administered *G. biloba* extracts at 100 mg/kg/day, a dose comparable to 6000 mg/day or greater in humans; however, most human studies incorporated doses of 240 mg/day or less.

Additionally, several studies have assessed the pharmacokinetics of ginkgolides and bilobalide in human volunteers. Following 240 mg doses of standardized *G. biloba* extracts, $C_{\max}$ values for ginkgolides and bilobalide rarely exceeded 40 ng/mL [381–383], concentrations well below the 4000 ng/mL at which ginkgolides A and B activated PXR *in vitro* [182]. It is possible that concentrations exceeding 40 ng/mL may be achieved within intestinal enterocytes, but this depends on disintegration and dissolution profiles of individual dosage forms (characteristics that can vary considerably between brands [384,385]), as well as the permeability of individual

terpene lactones or flavonol glycosides. In Caco-2 and MDR1-MDCK cell monolayers, ginkgolides and bilobalide exhibited low absorptive permeability and high efflux [386]; two conditions that would further preclude their exposure to enteric XMEs.

In summary, dosage forms containing standardized *G. biloba* extracts, when administered at doses of 240 mg/day or less, do not pose a risk for clinically relevant herb–drug interactions. However, daily doses exceeding 240 mg/day may increase prospects for interactions.

Risk: Low, at doses 240 mg/day or lower.

16.10.5 Ginseng

Of the five major *Panax* spp. worldwide, Asian ginseng (*Panax ginseng* C. A. Meyer) and American ginseng (*Panax quinquefolius* L.) are the most widely used and extensively studied. *P. ginseng* root has an almost 2000-year history of use in TCM as an adaptogen (a plant that increases resistance to stress and fatigue) and a restorative tonic. Today, ginseng root, either as a TCM or dietary supplement, is one of the most popular herbs in the world; used to improve libido and sexual performance, prevent cancer, regulate blood sugar, lower blood pressure, improve cognition, fight fatigue, and boost immunity [387]. With the possible exception of its mild hypoglycemic effect, ginseng's efficacy remains questionable, as many clinical trials have produced confounding results [388–390]. Ambiguity in clinical findings may be linked to differences in the ginsenoside content of products evaluated.

Ginsenosides, a group of triterpene glycosides (steroidal saponins), are unique to *Panax* spp. More than 40 ginsenosides have been identified in the roots of *P. ginseng* and *P. quinquefolius*. Ginsenoside nomenclature employs the designation Rx, where x represents the retention factor (Rf) value from the sequence of spots (from bottom to top) on thin-layer chromatography plates. Ginsenosides exhibit considerable structural variation. They differ from one another by the type, number, and site of attachment of sugar moieties. The two major subtypes of ginsenosides—protopanaxadiol and protopanaxatriol—are classified according to the arrangement and number of sugar (glucose, rhamnose, xylose, and arabinose) residues on the steroidal skeleton [391]. Rb1, Rb2, Rc, and Rd are examples of protopanaxadiol ginsenosides, while Re, Rf, Rg1, and Rg2 are examples of protopanaxatriols (Fig. 16.8). *P. ginseng* and *P. quinquefolius* differ significantly in type and proportion of ginsenosides, with *P. ginseng* having a high Rg1:Rb1 ratio and *P. quinquefolius* a low Rg1:Rb1 ratio [392]. Such distinctions may account for differences in purported efficacy between the two species. Ginseng root extracts are often standardized to contain a particular percentage (~4%) and ratio of ginsenosides. When ingested, ginsenosides undergo partial hydrolytic deglycosylation in the stomach and are further deglycosylated in the large intestine through enzymatic glucosidase activity of gut microflora [391,393–395]. It is these metabolites (e.g., Compound K, Fig. 16.8) that ultimately reach the systemic circulation and are alleged to have pharmacologic activity [393,395–397].

From a drug interaction perspective, clinical and nonclinical evidence regarding ginseng extracts and their effects on XMEs and transporters is particularly confusing. This confusion stems from an assortment of variables affecting ginsenoside disposition. These include, but are not limited to, variability in ginsenoside type and content [391,392], degree of preabsorptive deglycosylation [393–396], poor membrane permeability [398], interindividual differences in gut microflora [393–395], and enteric

efflux by ABC transporters [399,400]. It is now clear that highly polar, extensively glycosylated ginsenosides (e.g., Rb₁, Rb₃, Rg₃, Re, Rg₁, and Rg₂) are relatively weak modulators of human XMEs and transporters [162,179,329,401–408]. Ginsenoside concentrations necessary to inhibit most CYPs and transporters *in vitro* are not only high ($>50\mu\text{M}$), but are not likely to be realized *in vivo*, especially if normal dosing recommendations of ginseng products are followed [162,179,333,401–408]. This also holds true for the even higher ginsenoside concentrations ($>100\mu\text{M}$) required for inducing CYP1A1 [409], CYP2C9, and CYP3A4 [401] activity in human liver cells and microsomes. However, the products of ginsenoside hydrolysis (e.g., deglycosylated metabolites) have been shown to competitively inhibit a variety of CYPs and transporters, oftentimes at concentrations well below $20\mu\text{M}$ [404–409].

Only a limited number of animal studies have examined the effects of orally administered ginseng extracts ($>30\text{ mg/kg}$) on drug disposition. From these, it appears that *P. ginseng* or *P. quinquefolius* either mildly induce [410–412] or have no significant effects [413–415] on rat XMEs and ABCB1 activity *in vivo*. Substantially more prospective human trials have investigated the effects of *P. ginseng* and *P. quinquefolius* supplementation on human drug disposition, with the CYP2C9 substrate,

warfarin, being examined the most. Like the murine studies, clinical results fall into two categories: no effect [48,313,416–420] or mild induction [372,418,421,422].

Concerns regarding possible ginseng–drug interactions first surfaced when two case reports speculated that ginseng reduced warfarin anticoagulation [423,424]. As individual case reports cannot establish causation, a prospective clinical trial by Yuan *et al.* [422] demonstrated that international normalized ratios (INR, a measure of anticoagulation), peak plasma warfarin levels, and warfarin AUCs were reduced by *P. quinquefolius* in healthy volunteers, and these effects reached statistical significance. Subsequent clinical trials with *P. ginseng*, however, have failed to observe any influence on warfarin pharmacokinetics [372,417] or pharmacodynamics [372,417,419]. Such discrepancies may reflect the disparity in ginsenoside profiles between *P. ginseng* and *P. quinquefolius*; however, several methodological concerns have been raised about the Yuan *et al.* study including it being underpowered, that inadequate sampling was used to determine AUC, and a nonstereoselective assay was used to measure warfarin enantiomers [372]. Therefore, it appears that whatever effect(s) *P. quinquefolius* extracts might have on human CYP2C9 activity, their magnitude does not reach clinical significance. As a result, the available evidence that links ginseng supplementation to potentially harmful drug interactions remains unconvincing.

Interaction risk: Low.

16.10.6 Methylenedioxyphenyl-Containing Phytochemicals

The plant kingdom is replete with species that harbor phytochemicals whose structures contain methylenedioxyphenyl (MDP) moieties (Fig. 16.9). Popular botanical supplements known to contain substantial quantities of MDP-containing PSMs (MDP-PSMs) include goldenseal (*Hydrastis canadensis*), kava kava (*Piper methysticum*), black pepper (*Piper nigrum*), and *Schizandra* spp. In these species, MDP-PSMs often function as insecticides [40], but when consumed by humans they can act as mechanism-based inhibitors of CYPs [425,426]. This type of inhibition is thought to arise from CYP-dependent oxidation of the methylenedioxy carbon to a carbene that subsequently interacts with CYP heme iron to produce a stable heme-adduct, termed a *metabolic-intermediate* (MI) *complex* [426]. It is through the formation of MI complexes that CYP isoforms are inactivated by MDP-PSMs [426,427]. Because MDP-PSMs can function as mechanism-based CYP inhibitors, they too pose significant risks for herb-drug interactions.

Prolonged administration of MDP-containing compounds has also been shown to induce CYP1A and CYP2B expression in several animal species [426–428]. Induction of CYPs by MDP-PSMs may be mediated by AhR or through mechanisms that promote protein stabilization [427,428]. Whether CYP inhibition or induction predominates *in vivo* may depend on the length and bulk of MDP side chains as well as the individual CYP isoform examined [429]. MDPs with long bulky side chains appear to be more potent inhibitors of CYP1A2, CYP2C9, CYP2D6, and CYP3A4, whereas CYP2B6 and CYP2C19 are not inactivated [429].

16.10.6.1 Goldenseal. Extracts of goldenseal root (*H. canadensis* L.), a perennial herb indigenous to eastern North America, are often taken as an antimicrobial to prevent common colds and upper respiratory tract infections. Often formulated with *Echinacea* spp., goldenseal ranks among the top-selling botanicals in the United States.

Figure 16.9 Representative methylenedioxyphenyl-containing phytochemicals. (Broken circle = methylenedioxyphenyl moiety).

Goldenseal's medicinal properties are attributed to several isoquinoline alkaloids, of which berberine and hydrastine (Fig. 16.10) are the most prevalent. Both berberine and hydrastine are MDP-PSMs that inhibit various CYP isoforms *in vitro* [154,157,159,175,178,179,189]. Using fluorometric microtiter plate assays, Budzinski *et al.* [154] first noted that commercial extracts of *H. canadensis* were potent *in vitro* inhibitors of CYP3A4. Follow-up investigations by these authors found that goldenseal reduced CYP3A-mediated conversion of testosterone to its 6β-hydroxy metabolite by 88% [157]. Chatterjee and Franklin later confirmed the inhibition of testosterone 6β-hydroxylation by goldenseal extracts and extended their findings to include individual isoquinoline alkaloids [159]. They demonstrated that hydrastine was a more potent inhibitor of CYP3A4 ($IC_{50} = 25 \mu M$) than berberine ($IC_{50} = 400 \mu M$).

It is seldom that prospective clinical studies corroborate *in vitro*-based predictions of CYP-mediated herb–drug interactions; however, goldenseal appears to be an exception. Using phenotypic measures of CYP activity, Gurley *et al.* [248] first observed that goldenseal supplementation significantly inhibited CYP2D6 and CYP3A4 in healthy volunteers. In subsequent investigations with the CYP3A4 probe MDZ, Gurley *et al.* further demonstrated that 14 days of goldenseal supplementation (~209 mg isoquinoline alkaloids daily) significantly increased MDZ AUC, C_{max} , and elimination half-life, and that the effects were proportional to those produced by the well-recognized, mechanism-based inhibitor clarithromycin (1000 mg daily) [430]. In addition, goldenseal's inhibition of human CYP2D6 *in vivo* was confirmed with other commercially available supplement brands [273]. Interestingly, another prospective study evaluating the influence of goldenseal supplementation on the pharmacokinetics of indinavir (a protease inhibitor and CYP3A4 substrate) failed to register any significant effects [431]. This discrepancy may stem from the relatively

Figure 16.10 Representative phytochemicals (isoquinoline alkaloids) present in goldenseal.

high oral bioavailability of indinavir, which renders it a less effective probe for assessing herb-mediated changes in CYP3A activity. Thus, like GFJ furanocoumarins, goldenseal may have its greatest impact on those CYP3A substrates exhibiting high intestinal metabolism and low oral bioavailability.

In China, berberine (an OTC remedy for diarrhea of bacterial origin) has also been shown to significantly increase the AUC, $C_{\max}$, and trough concentrations of the immunosuppressive drug, cyclosporine [432,433]. Since cyclosporine is both a CYP3A4 and ABCB1 substrate, the activity of both of these proteins could conceivably be affected by hydrastine and berberine. There is convincing *in vitro* and animal evidence that berberine is a substrate for certain ABC isoforms [434–438], and thus, it may compete with other ABC substrates for efflux across intestinal and canalicular membranes. Recent clinical evidence, however, indicates that goldenseal's effect on digoxin (an ABCB1 substrate with a narrow therapeutic index) disposition in humans is not significant [439]. Therefore, goldenseal's likelihood for eliciting herb–drug interactions appears limited to those mediated by CYPs.

Dissolution profiles of commercially available goldenseal supplements reveal that berberine and hydrastine are rapidly and completely released from extract formulations (Gurley, 2010, Personal communication), producing intestinal luminal concentrations comparable to those required for CYP inhibition *in vitro* [430]. In humans, both berberine and hydrastine are readily absorbed and extensively metabolized, with berberine phase I metabolites being preferentially sulfated, while those of hydrastine are primarily glucuronidated [440]. Extensive metabolism is conducive to the formation of MI complexes and may explain goldenseal's penchant for CYP inhibition. Given that goldenseal isoquinoline alkaloids significantly inhibit both CYP3A4 and CYP2D6 activity (the two most important drug-metabolizing enzymes in humans), its herb–drug interaction potential is deemed considerable.

Interaction risk: High.

16.10.6.2 Kava Kava. Kava kava (*Piper methysticum* G. Forst.) has long been a traditional beverage consumed among South Pacific islanders to imbue psychotropic, hypnotic, and anxiolytic effects [441]. Since the 1990s, commercial kava extracts formulated as tablets and/or capsules have been marketed as dietary supplements for the alleviation of stress, anxiety, or insomnia [441,442]. Reports linking kava use to liver toxicity has led to the removal of these products from Australia, Canada, and several European countries, and prompted the FDA to issue warnings of possible hepatotoxic side effects associated with kava supplementation [441]. For those case reports documenting possible kava-related hepatotoxicity, prolonged usage (>60 days) and comedication with prescription drugs or other botanical supplements were frequent and confounding variables [441]. Modulation of human drug metabolism and/or transport has been postulated as an underlying mechanism for kava-induced liver toxicity. Accordingly, a significant body of literature exists exploring kava's ability to alter XME and transporter activity. The preponderance of *in vitro* data points to kava as an inhibitor of various CYPs and ABCB1 [155,156,161,442–446], whereas other evidence suggests that kava may activate PXR to induce CYP and ABCB1 activity [158,447,448]. In accordance to kava phytochemicals acting as nuclear receptor ligands, most studies that administered high doses of kava extracts to murine species for prolonged periods observed an induction in CYP1A and 3A activity and expression [445,449–452].

The kavalactones (e.g., kavain, dihydrokavain, methysticin, dihydromethysticin, yangonin, and desmethoxyyangonin) are a collection of phytochemicals unique to kava (Fig. 16.11). Of these, methysticin and dihydromethysticin are both MDP-PSMs and potent ($\leq 10\mu\text{M}$) mechanism-based inhibitors of CYPs *in vitro* [156,444]. Dihydromethysticin, like some other MDP-containing compounds, also appears to induce CYP3A isoforms *in vitro* through activation of human PXR [447]. In addition, both methysticin and dihydromethysticin have good dissolution profiles in simulated intestinal fluid at pH values >4 , a property favorable for producing gut lumen concentrations in excess of $10\mu\text{M}$ (Gurley, 2010, Personal communication). As a result, one might anticipate that kava supplementation would significantly modulate of human XMEs and transporters *in vivo*.

To date, only five prospective clinical studies have attempted to evaluate the drug interaction potential of kava and the results have been mixed [248,273,430,439,453]. Russman *et al.* found that in chronic users of traditional kava-containing beverages (e.g., 7–27 g kavalactones per week) CYP1A2 activity was significantly reduced, yet this practice had no effect on phenotypic markers of CYP2C19, 2D6, 2E1 or 3A4 function [453]. In contrast, Gurley *et al.* observed that 30 days of kava supplementation in healthy volunteers had no effect on phenotypic markers of CYP1A2, CYP2D6, or CYP3A4 activity, however, CYP2E1 activity was significantly reduced [248].

Discrepancies between these studies with regard to kava's effect on CYP1A2 and 2E1 may be traced to variations in extract composition. Traditional kava beverages are made from aqueous extractions of *P. methysticum* root, whereas formulations of many commercially available kava supplements are products of nonaqueous solvent extractions. Kavalactone profiles can vary considerably among the two extraction processes [442]. Subsequent studies conducted by Gurley's group found that, when compared to known CYP inducers and inhibitors, 14 days of supplementation with well-characterized kava products had no clinically relevant effects on human CYP2D6, CYP3A4, or ABCB1 activity [273,430,439].

Figure 16.11 Representative phytochemicals (kava lactones) present in kava kava.

The apparent low potency of methysticin and dihydromethysticin as mechanism-based inhibitors *in vivo* may stem from the structure of their MDP side chains. In examining a series of MDP-containing compounds, Nakajima *et al.* noted that those with short, nonbulky side chains were less effective inhibitors of CYP activity [429]. This, coupled with the fact that kava extracts often have lower amounts of methysticin and dihydromethysticin compared to the isoquinoline alkaloid content of goldenseal, may explain the difference in herb–drug interaction potentials for these two MDP-containing species. In short, consumption of commercially available kava supplements per product label recommendations is not likely to affect the efficacy or toxicity of conventional medications.

Interaction risk: Low.

16.10.6.3 Piperine/Black Pepper. Dried ground black pepper (*Piper nigrum* L.) has been used since antiquity as both a flavoring agent and medicine [454]. In fact, for almost two millennia *Piper* spp. (e.g., *P. nigrum* and *P. longum*) have been essential components of several ayurvedic medicine preparations [455]. Black pepper is one of the most commonly used spices and may be found on nearly every dinner table in the industrialized world. Black pepper is produced from green unripe berries of the pepper plant; the fruits are dried following a heat treatment that releases browning enzymes from the cell walls [456]. The spiciness of black pepper is because of the MDP-containing phytochemical, piperine, and related pungent alkaloids known as

Figure 16.12 Representative phytochemicals (piperamides) present in black pepper.

piperamides [454] (Fig. 16.12). These compounds function as insecticides in the pepper plant [457–459], but in mammalian systems they are inhibitors of various XMEs [460–471] and transporters [186,187,472–475]. While inhibition is clearly the most prevalent finding, especially on acute exposure, several animal studies report upregulation of GSTs [476], certain CYPs [477,478], and ABCs [186,472,474] with long-term exposure to piperine, a finding in line with other studies examining chronic feeding of MDP-PSMs.

Piperine's ability to inhibit drug metabolism was first recognized by Atal *et al.* [460] more than 30 years ago when its administration to rats increased the oral bioavailability of the alkaloids sparteine and vasicine by factors of two and three, respectively. In addition, piperine increased the pharmacodynamic effects of hexobarbital and zoxazolamine in a dose-dependent manner [460]. Follow-up studies by Atal's group observed that piperine administration was a noncompetitive inhibitor of various murine hepatic monooxygenases as well as UGTs [461]. Subsequent studies confirmed piperine's effect on murine XMEs [462–467,470] and also found that it and other piperamides were selective inhibitors of human CYP3A4, CYP2D6, and ABCB1 *in vitro* [187,468,469,471]. Piperine's inhibitory effect on UGTs is more pronounced in intestinal epithelial cells than hepatocytes [464]. Moreover, structure–activity relationship studies involving more than 35 separate analogs revealed that piperine is especially suited for CYP inhibition [467]. Modifications to either the MDP moiety or piperidine side chain significantly reduced its potency [467]. (Millions of years of plant–animal warfare have clearly optimized piperine pharmacology.) In addition to its inhibitory effects on XMEs and ABCB1, piperine may also promote drug absorption by modulating the permeability characteristics of intestinal membranes as well as through stimulating increases in microvilli length [479].

One of the most compelling aspects of piperine is its ability to dramatically enhance the oral absorption of concomitantly administered medications [460,473,475,480–485] (Fig. 16.13). To date, every prospective human trial investigating black pepper's and/or piperine's effect on drug pharmacokinetics has demonstrated a profound improvement in oral bioavailability. Drugs affected and the observed percent increase in mean AUC include phenytoin (16–133%) [481,483,484], rifampicin (69%) [480], propranolol (103%) [482], theophylline (96%) [482], and nevirapine (170%) [485]. In practically every case, piperine's effect can be considered clinically relevant. This is especially so for drugs with narrow therapeutic indices.

Figure 16.13 Plasma concentration–time curve for nevirapine in healthy subjects when coadministered with piperine (■) or placebo (○). (Mean $\pm$ standard error).

Recognizing piperine's utility as a bioavailability enhancer, many dietary supplement manufacturers incorporate *P. nigrum* or *P. longum* extracts into botanical formulations as a means of improving phytochemical efficacy. This positive herb–herb interaction is best exemplified by curcumin, a dietary phytochemical in tumeric with promising chemopreventative properties but exceedingly poor oral bioavailability due to extensive CYP- and UGT-mediated metabolism [486,487]. When administered with 5 mg of piperine, a twofold increase in curcumin AUC was observed in healthy volunteers [486]. In another study, 20 mg of piperine produced an almost 20-fold increase in curcumin AUC [488]. Similar bioavailability enhancing effects on green tea polyphenols have also been reported [489]. As an added benefit to enhancing phytochemical bioavailability, piperine also has a broad safety profile [454].

When used in quantities typical for flavoring food, black pepper is not likely to affect the disposition of most medications. However, excessive use of black pepper or intake of dietary supplements formulated with *P. nigrum* or *P. longum* extracts may produce clinically significant interactions with drugs. This may be of particular concern when CYP3A and/or ABCB1 substrates are ingested concomitantly with piperine or piperamides in excess of 10 mg.

Interaction risk: High.

16.10.6.4 *Schisandra* spp. Preparations of fruits from woody vines in the family Schisandraceae are a staple in traditional Chinese, Japanese, and Russian medicine [490]. Among their many uses, berry extracts of *Schisandra* spp. (e.g., *S. chinensis* (Turcz.) Baill. and *Schisandra sphenanthera* Rehder & E. H. Wilson) are often prescribed for their adaptogenic and hepatoprotective properties [490,491]. In the United States, extracts of *S. chinensis* and *S. sphenanthera* are often incorporated into multi-component dietary supplement formulations.

A host of unique MDP-PSMs including gomisins A-C, schisandrin, schisandrol B, and schisantherin D are found in *Schisandra* spp. (Fig. 16.14). Like many MDP-PSMs, those present in *Schisandra* spp. are modulators of mammalian XMEs and transporters. Recognition of these properties is important as *Schisandra* products are often taken in conjunction with conventional medications in China, Japan, Russia, and

Figure 16.14 Representative methylenedioxyphenyl-containing phytochemicals present in *Schisandra* sp.

other Asian countries. In addition, dietary supplements containing *Schisandra* extracts are becoming more popular in many Western cultures. This too may increase the chance of *Schisandra*-related herb–drug interactions.

Ample evidence points to *Schisandra* MDP-PSMs as both substrates and inhibitors of ABC efflux transporters *in vitro* [492–498]. A number of *in vitro* studies also point to *Schisandra* MDP-PSMs as both competitive and noncompetitive inhibitors of human CYP isoforms [160,167,499–502]. In particular, gomisins B, C, and G were shown to be particularly effective inhibitors of human CYP3A4 with IC_{50} values $<1.5\ \mu\text{M}$ [167]. In the presence of NADPH, gomisin C's inactivation of CYP3A4 was time- and concentration-dependent, as well as irreversible, characteristics indicative of mechanism-based inhibition. Moreover, the inhibitory effect of gomisin C was stronger than that of ketoconazole, a known potent CYP3A4 inhibitor [167]. In contrast, reporter gene assays demonstrated that *S. chinensis* extracts and the individual constituents schisandrin and schisandrol activated rat and human PXR [500], whereas certain natural gomisin H analogs (e.g., tigloylgomisin H and angeloylgomisin H) significantly activated phase II detoxification gene expression via the Nrf2 nuclear receptor pathway [503].

Of the available animal studies investigating *Schisandra*'s effect on xenobiotic metabolism, two outcomes emerged (inhibition or induction), each dependent on the duration of administration. When single doses of *Schisandra* extracts ($\leq 250\ \text{mg/kg}$) were administered to rats concomitantly with CYP3A and/or ABCB1 substrates (e.g., MDZ [501], nifedipine [499], paclitaxel [504], and tacrolimus [502]), drug AUCs more

than doubled suggestive of inhibition. However, when administration period exceeded six days, rat XME and transporter function was consistently induced [500,501,505,506].

Unlike the murine study results, prospective clinical trials assessing *Schisandra*'s effect on CYP3A and/or ABCB1 substrate pharmacokinetics were not biphasic. Whether *Schisandra* was administered once or for up to 14 consecutive days, AUCs of talinolol (ABCB1 substrate) [376], tacrolimus (CYP3A4/ABCB1 substrate) [507,508], and MDZ (CYP3A4 substrate) [509] were increased 1.5-, 2.1-, and 2.0-fold, respectively. On the basis of these data, it appears that *Schisandra* is a potent inhibitor, not an inducer, of human XMEs and transporters. Such species differences may stem from the fact that humans not only received lower milligram per kilogram doses of *Schisandra*, but that gomisins C concentrations necessary for PXR activation in humans were twice that required for murine species [501]. Accordingly, the currently available clinical data strongly suggests that *Schisandra* extracts pose a significant risk for elevating blood levels of drugs that are CYP3A and/or ABCB1 substrates.

Interaction risk: High.

16.10.7 Milk Thistle

Silybum marianum L. Gaertn., commonly known as *milk thistle*, is an herbaceous plant native to the Mediterranean region, although it has been naturalized throughout the world [510]. Extracts of milk thistle fruits (achenes) yield a collection of flavanolignans and flavonoids collectively known as *silymarin* [510,511]. The principal phytochemical components in silymarin are silybin A, silybin B, isosilybin A, isosilybin B, silychristin, isosilychristin, silydianin, and taxifolin [511] (Fig. 16.15). Milk thistle extracts are touted for their antioxidant and hepatoprotectant properties, and their utility as therapy for treating various liver diseases (e.g., cirrhosis, hepatitis, and hepatotoxicity) has been examined in numerous clinical trials [512–516]. While many smaller trials have revealed improvements in various clinical indices, several larger studies have yielded equivocal results. However, an unequivocal conclusion gleaned from the clinical studies is that milk thistle has an excellent safety profile [512–516].

Milk thistle is one of the few popular botanicals in which the pharmacokinetic profile of its principal phytochemicals has been thoroughly examined in humans [517–521]. Components of standard milk thistle extracts, as a general rule, have very low oral bioavailability and short elimination half-lives. This stems from a combination of the poor water solubility of silymarin phytochemicals coupled with extensive presystemic metabolism (both phase I and II) and biliary secretion. As an example, $C_{\max}$ values for unconjugated silybin A and B (the two most prevalent flavanolignans in milk thistle products) rarely exceeded 20 ng/mL for single 600 mg doses of milk thistle extract in healthy volunteers [520]. Even when milk thistle extract (700 mg) was administered every 8 h for seven days, the maximum steady state concentrations of silybin A and B rarely exceeded 1.5 μ g/mL [521]. At doses exceeding 1500 mg daily, there was also evidence of nonlinear pharmacokinetics [521]. Liver disease, however, does increase milk thistle flavanolignan exposure. Systemic concentrations of silybin and isosilybin diastereomers may be three- to fivefold higher in patients with cirrhotic or nonalcoholic fatty liver disease, which may account for milk thistle's purported efficacy in these populations [519,521].

Given its popularity as one of the most utilized botanical supplements in the world, milk thistle's ability to modulate human XMEs and transporters has received

Figure 16.15 Representative phytochemicals (flavanolignans) present in milk thistle.

considerable attention. A variety of *in vitro* methodologies have been utilized to assess the effect of milk thistle extracts or individual flavanolignans on XME [174,178,179,189,522–530], ABC efflux transporter [174,178,179,527,531–536], and SLC1B1 uptake transporter [537] activity. The majority of studies are in general agreement that flavanolignan concentrations in excess of 10 μM are required for inhibition of most CYP isoforms and even higher concentrations are needed for ABCB1 and ABCG2 inhibition. Of all the CYP isoforms tested, CYP2C9 appears to be the most sensitive with IC_{50} values $\sim 8 \mu\text{M}$ for human liver microsomes. At concentrations exceeding 30 μM , silybin diastereomers have been reported to function as mechanism-based inhibitors of CYP2C9 and 3A4 [526]. UGT1A1, however, may

be the XME most easily inhibited by milk thistle with an IC_{50} value of $1.4 \mu M$ [526]. SLC1B1 also exhibited an IC_{50} value $<4 \mu M$ for silymarin [537].

Because milk thistle flavanolignans exhibit poor oral bioavailability, several technologies have been employed to enhance this property [538]. One of the more successful has been complexation of silymarin components with phosphatidylcholine. Marketed as Silipide[®] and Siliphos[®], these phosphatidylcholine complexes, or phytosomes, exhibit improvements in flavanolignan bioavailability three to five times that of conventional milk thistle extract formulations [538–542]. In addition, recent clinical studies in prostate cancer patients have shown that doses of Siliphos ranging from 2.5 to 20 g daily for up to four weeks produced C_{max} values between 10 and $100 \mu M$ for unconjugated silybin diastereomers [543,544]. Conceivably, these concentrations are sufficient for inhibition of various XMEs and efflux transporters, and episodes of hyperbilirubinemia reported in these studies may indeed reflect inhibition of UGT activity [543,544].

To date, a considerable number of prospective human studies have examined milk thistle's drug interaction potential. Supplementation regimens utilizing standard milk thistle extracts had no observable effects on the clinical pharmacokinetics of aminopyrine (nonspecific CYP probe) [545], caffeine (CYP1A2 probe) [115], chlorzoxazone (CYP2E1 probe) [115], debrisoquine (CYP2D6 probe) [115,273], digoxin (ABCB1 substrate) [247], indinavir (CYP3A4 substrate) [546–548], irinotecan (CYP3A4/UGT1A1 substrate) [549], MDZ (CYP3A4 probe) [115,229], nifedipine (CYP3A4 substrate) [550], phenylbutazone (nonspecific CYP probe) [545], ranitidine (CYP3A4/ABCB1 substrate) [551], and rosuvastatin (ABCB1/SLC1A1 substrate) [537]. Taken together, these findings imply that standard milk thistle products generate flavanolignan concentrations *in vivo* that are incapable of affecting most human XMEs and transporters. However, a few clinical studies challenge this assumption. For example, 14 days of silymarin supplementation (140 mg, thrice daily) increased the AUC of talinolol (ABCB1 substrate) in healthy volunteers by 36% (a finding suggestive of ABCB1 inhibition); however, this effect is not considered clinically relevant [552]. In contrast, 140 mg of silymarin administered to healthy adults for nine days reduced the mean AUC for metronidazole (CYP3A4/ABCB1 substrate) by 29% [553], and while this effect hints at possible induction, it too is considered clinically insignificant. More concerning is a recent finding that silymarin inhibits the metabolism of losartan to its active metabolite E-3174, and that the magnitude of the interaction is dependent on *CYP2C9* genotype [149]. In subjects with the *CYP2C9**1/*1 genotype, a 14-day course of silymarin produced a twofold increase in losartan AUC and C_{max} , but these parameters were not affected in subjects with the *CYP2C9**1/*3 genotype. This finding supports that of Brantley *et al.* [530] who noted that *CYP2C9* appeared most vulnerable to inhibition by clinically achievable concentrations of silybin B.

At present, no prospective studies have examined the effects of phytosomal milk thistle preparations on the pharmacokinetic profiles of conventional medications. As such, it remains to be seen whether milk thistle products with enhanced bioavailability pose a greater risk for herb–drug interactions. A recent clinical trial of Siliphos for the treatment of chemotherapy-related hepatotoxicity in childhood acute lymphoblastic leukemia suggests otherwise, as investigators observed no adverse interactions between milk thistle and methotrexate, 6-mercaptopurine, or vincristine during the 28-day course of supplementation [554]. Therefore, based on the collective clinical data currently available, the drug interaction risk for milk thistle products appears minimal.

Interaction risk: Low.

16.10.8 St. John's Wort

With more than 2000 peer-reviewed articles published on its safety and efficacy, SJW (*H. perforatum* L.) is the most studied botanical dietary supplement in the world. *H. perforatum* is a yellow-flowering, perennial herb indigenous to Europe that has been introduced to many temperate areas of the world and grows wild in many meadows. The common name comes from its traditional flowering and harvesting on 24 June, the birthday of John the Baptist (St. John's Day).

Extracts of *H. perforatum* have gained international recognition for their antidepressant activity although the efficacy of many SJW products remains questionable [555]. Nevertheless, many clinical trials have demonstrated efficacy superior to placebo and comparable to standard antidepressants, but with fewer side effects than conventional antidepressive agents [556]. When used as a single agent, a favorable risk/benefit ratio has made SJW one of the most readily consumed dietary supplements in the world. In turn, the popularity of SJW has also contributed to its distinction as being one of the most problematic dietary supplements with regard to herb–drug interactions.

Both the antidepressant effect and drug interaction potential of SJW hinge on the extract's content of hyperforin, a bicyclic polyprenylated acylphloroglucinol found exclusively in *Hypericum* spp. [557] (Fig. 16.16). As an antidepressant, hyperforin functions as broad-based neurotransmitter reuptake inhibitor, affecting the synaptosomal uptake of serotonin, dopamine, norepinephrine, glutamate, and γ -aminobutyric acid with similar efficiency. Hyperforin's mode of action appears unique in that the phytochemical does not interact directly with uptake transporters but elevates intracellular sodium concentration, thereby inhibiting gradient-driven neurotransmitter reuptake [557]. As previously mentioned in Section 16.4.1, recent investigations reveal that hyperforin and other SJW-related phytochemicals (e.g., adhyperforin, hypericins, and flavanol glycosides) act synergistically through both pharmacodynamic and pharmacokinetic mechanisms to alleviate depression [190].

Figure 16.16 Representative phytochemicals (phloroglucinols, naphthodianthrone, and flavanol glycosides) present in St. John's wort.

Figure 16.17 Effect of St. John's wort on cyclosporine trough concentrations in renal transplant recipients who did not (a) and who did (b) develop graft rejection. Broken lines represent cyclosporine therapeutic range. Reprinted with permission [558].

While recognized as a natural antidepressant, SJW is equally well known for its ability to induce the activity of several XMEs and transporters, thereby reducing the efficacy of a multitude of prescription medications. As discussed earlier in Section 16.7.3, the clinical severity of SJW-mediated interactions was first recognized in 1999–2000. At that time, several clinics around the world reported that concomitant use of SJW and cyclosporine produced dramatic reductions in blood levels of the immunosuppressant among organ transplant recipients resulting in graft rejection (Fig. 16.17) [208–210,558]. Since that time a plethora of clinical studies have borne out SJW's effect on the pharmacokinetics of various medications [226,559–562].

Hyperforin, a principal mediator of SJW's antidepressive action, lies at the heart of the herb's drug interaction potential. The prenylated phloroglucinol is a high affinity ligand for human PXR, an orphan nuclear receptor selectively expressed in the liver and intestine that mediates the induction of XME and efflux transporter gene transcription [211,212,563]. According to one estimate, hyperforin is the most potent

PXR activator discovered to date [211], with a half-maximal effective concentration (EC₅₀) of 23 nM—a value well below plasma concentrations often achieved in humans (~100–300 nM) [564,565]. (Unlike many of the unique phytochemicals described previously, hyperforin is bioavailable and exhibits an elimination half-life of 8–12 h, thus allowing for significant accumulation with repeated dosing [564,565].) Of the XMEs and transporters regulated by PXR, those most affected by SJW are CYP subfamilies 2C and 3A as well as several ABC efflux transporters [559–562]. As a result, more than 70% of all prescription medications are susceptible to SJW-mediated interactions, the consequences of which are decreased oral bioavailability, enhanced systemic clearance, and reduced drug efficacy.

As with all botanicals, phytochemical content can vary considerably (Section 16.7.4) and such is the case with hyperforin [566,567]. Most SJW extracts are currently standardized to contain 3% hyperforin, yet many brands may possess amounts well below this value. Several clinical studies have demonstrated that SJW extracts containing <1% hyperforin are less likely to produce clinically relevant herb–drug interactions [567–570]. Unfortunately for consumers, few SJW products are specifically labeled as having low hyperforin content. Accordingly, to avoid significant drug interactions, consumers should avoid concomitant use of SJW and prescription medications.

In addition to content variability, another factor affecting the magnitude of hyperforin's effect on CYP3A expression and drug efficacy is PXR haplotype. Like many CYPs, PXR is polymorphic, and certain mutations produce significant functional defects in terms of CYP3A transcription. Recent studies indicate that individuals with the H1/H1 haplotype pair appear more susceptible to SJW-mediated CYP3A induction than subjects with H1/H2 or H2/H2 pairings [571]. Furthermore, once SJW has been discontinued, as much as a week may be required before CYP3A activity returns to basal levels [572].

SJW's penchant for producing herb–drug interactions has been scrutinized in several recent reviews [226,559–562]. Table 16.2 summarizes those drugs in which SJW produces clinically significant interactions.

Interaction risk: High.

16.11 CONCLUSIONS AND FUTURE PERSPECTIVES

Millions of years of “plant–animal warfare” have led to a complex and proficient system of human XMEs and transporters that work in concert to preclude absorption and facilitate elimination of numerous structurally diverse dietary phytochemicals. As a result, most plant-based foods and dietary supplements pose only minimal risks for modulating human drug metabolism. However, several distinct PSMs can either inactivate or hijack the controls of this innate gastrointestinal defense network. PSMs such as GFJ furanocoumarins, functioning as mechanism-based inhibitors of CYPs, may potentiate the toxicity of allopathic medications, whereas potent nuclear receptor ligands such as hyperforin may dramatically reduce drug efficacy. What differentiates these PSMs as significant modulators of human drug disposition from the multitude of others is their combination of favorable physicochemical properties and unique pharmacophores. As discussed in previous sections, many PSMs modulate human XMEs and transporters *in vitro*, but because of various factors, this activity is rarely realized *in vivo*.

Recognizing that poor dissolution characteristics represent major obstacles to phytochemical bioavailability and efficacy, several dietary supplement manufacturers have recently incorporated novel methods of formulating botanical extracts as a means of improving oral absorption. Such innovative formulation technologies include liposomes, self-emulsifying microemulsions, microspheres, phosphatidylcholine complexation (phytosomes), and nanoparticles [604], as well as incorporation of piperine as a CYP3A4 and ABCB1 inhibitor [468,469]. In each instance, when compared to conventional extract formulations, the oral bioavailability of various phytochemicals can be increased several fold [604]. To date, no clinical assessments of the herb–drug interaction potential of botanical extracts incorporating these novel formulations have been reported. Accordingly, many botanicals whose drug interaction potential is minimized when administered as conventional dry extracts may increase significantly on ingestion of formulations utilizing novel delivery systems. Phytochemicals that heretofore had been casualties of man’s xenobiotic defense system may emerge as inducers and/or inhibitors of human XMEs and transporters. Improved phytochemical delivery, therefore, may open up a new theater of operations in the “drug war” between humans and plants.

Currently, thousands of botanical supplements are available in the United States and abroad, and hundreds of new products are introduced onto the market each year. Not surprisingly, the vast majority of these botanicals have yet to be evaluated in a clinical setting. From a practical perspective, most may not warrant clinical study; logistics alone clearly preclude such an endeavor. Nevertheless, *in vitro* studies and compelling case reports suggest that many more botanical supplements may indeed be potent modulators of human drug disposition.

17.1 SUMMARY

Idiosyncratic drug reactions (IDRs) are adverse drug reactions (ADRs) that are not related to the known pharmacological properties of the drug, occur in only a small percentage of the population (accounting for 6–10% of all ADRs), and do not show any apparent dose–response relationship. The unpredictable nature of IDRs together with the often serious adverse effects encountered, pose a major health concern in the development and clinical usage of pharmaceuticals. As opposed to direct toxicity, which generally occurs rapidly following drug exposure, IDRs typically have a delayed onset of reaction following drug administration and may involve various organs, including liver, skin, bone marrow, or may be a generalized systemic response. The mechanism of IDRs is not clearly understood and is the subject of considerable debate. Several theories have been proposed, but IDRs can be generally categorized mechanistically as either immune-mediated or nonimmune-mediated. Currently, the major hypotheses for the mechanism behind the development of IDRs include the hapten hypothesis, the reactive metabolite hypothesis, the metabolic idiosyncrasy hypothesis, the pharmacological interaction (p-i) concept, the danger hypothesis, the mitochondrial injury hypothesis, and the inflammagen hypothesis. For both immune-mediated and nonimmune-mediated mechanisms, there is circumstantial evidence that reactive metabolites play a role in IDRs. In general, most drugs that cause idiosyncratic reactions are not sufficiently reactive in themselves, but most are metabolized to chemically reactive metabolites

that may covalently bind to cellular proteins. Recent investigations continue to support the association of reactive metabolites and immune-mediated responses with IDRs. In drug development, IDRs can lead to drug failure, which is further complicated by the difficulty in predicting the clinical risk of IDRs and by the ineffectiveness of current nonclinical toxicity testing strategies to identify drugs that may potentially cause an IDR. Investigations in animal models have had limited success owing to the unpredictability of IDRs in animals, which is similar to the situation in humans. However, IDRs in animals do share some characteristics and mechanisms observed in humans, supporting the need for further study of animal models. Examples of animal models that most closely reflect human IDRs include sulfonamide hypersensitivity in dogs, nevirapine rash in rats, propylthiouracil (PTU)-induced autoimmunity in cats, and D-penicillamine autoimmunity in Brown Norway (BN) rats. Although attempts with other animal models, such as procainamide-induced lupus and felbamate-induced liver toxicity and aplastic anemia, have been unsuccessful to date, they are examples of compounds where reactive metabolites are thought to play a role in ADRs and may provide some insight into possible mechanisms that may be relevant to IDRs. As evidenced from the many hypotheses that have been proposed, the mechanisms involved in the occurrence of IDRs are complex and the development of appropriate animal models will be key to developing a better understanding of the basic underlying mechanisms involved in IDRs.

17.2 INTRODUCTION

ADRs are among the top 10 leading causes of death [1,2]. It is estimated that 100,000 deaths per year are attributed to ADRs [3]. They are a major contributor to hospitalization throughout the world and have resulted in health care costs in excess of \$3.6 billion annually [1,4,5]. Drugs most frequently associated with ADRs are diuretics, opioid analgesics, antipsychotics, anticoagulants, and antirheumatism drugs [4–7]. A secondary outcome to ADRs is often the immediate removal of the drug from the market with the consequent loss of a potentially promising new medicine and the associated financial costs to the pharmaceutical industry [8,9]. Troglitazone and felbamate are two examples of drugs that either have been withdrawn or have restricted usage because of ADRs [10–12].

ADRs can be variably classified as predictable or unpredictable [13]. Type A ADRs are predictable, attributed to an augmented primary or secondary pharmacological effect, and are usually dose dependent; whereas, type B ADRs are considered unpredictable or idiosyncratic [13–15]. IDRs are also referred to as *drug-induced hypersensitivity reactions* or *allergic reactions*. IDRs are ADRs that are not related to the known pharmacological properties of the drug, occur in only a small percentage of the population, and do not show any apparent dose–response relationship [13,16]. Type A ADRs are more common than type B ADRs, accounting for >80% of ADRs, whereas IDRs (i.e., type B ADRs) are rare, occurring with an incidence ranging from 1 in 100 to 1 in 100,000 [17,18]. Although the incidence of IDRs is not as high as type A ADRs (IDRs accounting for 6–10% of all ADRs), the occurrence of IDRs is still of considerable concern because of the number of drugs involved, the number of people taking these drugs, and the unpredictable and serious nature of the ADRs that may account for many drug-related deaths [13,16,19,20]. IDRs can be very serious

medical conditions when manifested as hepatotoxicity, hemolytic anemia, agranulocytosis, erythema multiforme, toxic epidermal necrolysis (TEN), or Stevens–Johnson Syndrome (SJS) [13,21–24]. IDRs are generally drug and individual specific [16,25]. Genetic variants that cause susceptibility to a drug reaction are becoming increasingly more important in understanding the potential causes of ADRs [26].

In drug development, IDRs can lead to drug failure, which is further complicated by the difficulty in predicting the clinical risk of IDRs and by the ineffectiveness of current nonclinical toxicity testing strategies to identify drugs that may potentially cause an IDR [16]. Investigations in animal models have had limited success owing to the unpredictability of IDRs in animals, which is similar to the situation in humans. However, IDRs in animals do share some characteristics and mechanisms observed in humans, supporting the need for further study of animal models [27,28].

17.3 CHARACTERISTICS AND MECHANISMS OF IDIOSYNCRATIC DRUG REACTIONS

As opposed to direct toxicity, which generally occurs rapidly following drug exposure, IDRs typically have a delayed onset of reaction following drug administration and may involve various organs, including liver, skin, bone marrow, or may be a generalized systemic response. In most cases, this delay is in the order of a week or more following first exposure, but on occasion, may occur within days of administering the first dose of drug [16]. For example, the delay in onset of idiosyncratic drug-induced hepatitis may be more than a year for troglitazone [29]. However, on rechallenge, the time of onset for many drugs may be much shorter and may even be in the order of minutes for an anaphylactic reaction [16]. IDRs can occur when there is a convergence of risk factors, which may involve both drug-related risk factors (e.g., metabolism, bioactivation, covalent binding, and inhibition of key cell functions) and patient-related risk factors (e.g., age, sex, concurrent disease, comedications, nutritional status, immune function, physical condition, and genetic predisposition)[30,31].

The mechanisms of IDRs are not clearly understood and are the subject of considerable debate. Several theories have been proposed, but IDRs can be generally categorized mechanistically as either immune-mediated or nonimmune-mediated [16,32]. Currently, the major hypotheses for the mechanism behind the development of IDRs include the hapten hypothesis, the reactive metabolite hypothesis, the metabolic idiosyncrasy hypothesis, the pharmacological interaction (p-i) concept, the danger hypothesis, the mitochondrial injury hypothesis, and the inflammagen hypothesis [33,34]. In the hapten hypothesis, small molecules (e.g., a drug or a chemically reactive metabolite) themselves are not immunogenic, but when a small molecule (i.e., hapten) is bound irreversibly to protein, the modified protein acts as an immunogen to elicit an immune response [35]. The reactive metabolite hypothesis proposes that while most reactive metabolites are detoxified, when detoxification systems (e.g., glutathione (GSH)) become depleted, reactive metabolites can act as haptens, which fits with the hapten hypothesis [34]. In some cases of IDRs, particularly those involving idiosyncratic liver toxicity, characteristics of an immune-mediated reaction (i.e., fever, rash, eosinophilia, antidrug antibodies) are not present. In these cases, the metabolic idiosyncrasy hypothesis postulates that the drug-metabolizing polymorphism may be a risk factor, although clear evidence of the polymorphism being responsible for the idiosyncratic nature of

an IDR is lacking [34]. In the p-i concept, it is proposed that some drugs are able to initiate an immune response by reversible interaction with the major histocompatibility complex (MHC) or the T-cell receptor and that this interaction more closely resembles a pharmacological response [36]. The danger hypothesis postulates that the immune system responds with tolerance to most foreign antigens, and that an immune response is triggered by an innate “danger signal” rather than by the foreign antigen [18,37–41]. Although the exact nature of the stimuli that trigger a “danger signal” is not entirely certain, it is plausible that cell damage or cell stress (e.g., heat shock proteins) is a major stimulus with consequent activation of antigen-presenting cells (APCs) [34]. In the mitochondrial injury hypothesis, heterozygous mice deficient in mitochondrial superoxide dismutase (complete deficiency is lethal) treated with troglitazone or flutamide developed a delayed-onset hepatotoxicity [42,43]. This is a very attractive model because, unlike many models, the toxicity is delayed in onset, thereby mimicking clinical idiosyncratic hepatotoxicity [33]. The inflammagen hypothesis proposes that “inflammagens,” such as lipopolysaccharide (LPS), which we are commonly exposed to, in combination with a drug (e.g., ranitidine) can result in drug-induced idiosyncratic hepatotoxicity [44–46].

On the basis of the characteristic delay observed between initiation of drug administration and the onset of the adverse reaction and the decreased delay observed following rechallenge, many IDRs appear to be immune-mediated [27,47–50]. Clinically, immune-mediated events are sometimes manifested by blood and tissue eosinophilia associated with fever, which subside quickly following drug withdrawal, unless there is progression to drug-induced autoimmunity [25]. For both immune-mediated and nonimmune-mediated mechanisms, there is circumstantial evidence that reactive metabolites play a role in IDRs [14,27]. In general, most drugs that cause idiosyncratic reactions are not sufficiently reactive in themselves, but most are metabolized to chemically reactive metabolites that may covalently bind to cellular proteins [27]. However, covalent binding to a protein is not in itself enough to cause an IDR since many drugs or metabolites that bind to proteins do not result in a significant incidence of IDRs [51].

Although many consider IDRs to be dose independent, an increase in incidence of IDRs may be seen with increasing dose within the therapeutic range for many drugs consistent with a dose–response relationship [16,52,53]. Although most IDRs are associated with a clinical dose range, there is almost always a dose level that will not elicit an IDR. There is evidence that IDRs rarely occur with drugs administered at doses less than 10 mg/day, which suggests that there is a threshold for the most common types of IDR [16].

Another characteristic of IDRs is adaptation or tolerance, in which clinical symptoms ameliorate or completely resolve in the face of continued treatment, particularly in situations where a low dose is administered initially, followed by dose escalation [14,16]. The reduced risk of developing an IDR clinically may be attributed to the low dose being insufficient to trigger an idiosyncratic reaction but sufficient to induce immune tolerance [14]. In a murine model of 2,4-dinitrochlorobenzene (DNCB)-induced delayed-type hypersensitivity (DHT) reaction, hepatic Kupffer cells (KCs) were shown to play an important role in mediating tolerance against drug–protein adducts. KCs were found to suppress T-cell activation by the production of prostaglandins (PGE₂ and 15 d-PGJ₂). These findings suggest that KCs, in addition to regulating immune reactions in the liver, may play a role in liver-mediated systemic

immune tolerance [54]. Furthermore, any factors (e.g., genetic and environmental) that can impair hepatic KC function leading to decreased production of prostaglandin may result in an increased risk of developing IDRs [55].

IDRs share characteristics and pathology with other disease processes, which makes diagnosis difficult. For example, hepatic IDRs may present with a similar histopathologic appearance as viral hepatitis or idiopathic hepatitis, which precludes identification of the cause or initiating events [16]. The inflammatory response in the liver in these cases may appear similar but is not pathognomonic for the cause of the hepatitis. However, eosinophilia in cases of hepatitis is considered evidence of an immune-mediated response consistent with hepatic IDR. Similarly, the cause of most IDR-induced skin rashes cannot be readily differentiated from viral or other causes unless they present with specific diagnostic features as those that occur in fixed drug eruptions or TEN, which are pathognomonic for an idiosyncratic drug response [16].

Other risk factors identified for IDRs include sex, age, weight, and disease state. However, these factors appear to be associated with specific IDRs [16]. Although women appear to be at increased risk for IDRs caused by some drugs (e.g., halothane-induced hepatitis) and for idiopathic autoimmune reactions (e.g., lupus and autoimmune thyroid disease), other autoimmune diseases, such as type 1 diabetes, do not have such a female predominance [16,56]. Similarly, while the risk of drug-induced liver toxicity (e.g., isoniazid and acetaminophen) increases with age, the risk of valproic acid liver toxicity is greater in children than adults [16]. Halothane-induced hepatotoxicity occurs more commonly in obese patients, which is attributed to the distribution of halothane to fat, thereby requiring higher doses of drug to achieve effect [56]. Although it is generally believed that preexisting liver disease does not increase susceptibility to hepatic IDRs, there appears to be exceptions to this dogma [16,57]. Patients with hepatitis C appear to be at greater risk for developing veno-occlusive disease following myeloablative therapy [58]. Other types of diseases associated with increased risk of IDRs include mononucleosis [59], HIV infection [60], and human herpesvirus 6 infection [61].

Although the acute hepatotoxic effects of some drugs, for example, acetaminophen, are well understood and clearly dose dependent, there are many other drugs that are potentially hepatotoxic at therapeutic doses, for which the key susceptibility factors are not known [62]. An underlying disease state can further complicate and influence the toxic response to a drug through modulation of toxicokinetics (e.g., metabolism, disposition, and clearance) or altered expression of key genes by a disease that may render an individual more susceptible to a drug's adverse effects [62]. Mice subjected to environmental stress through immobilization in restraint cages demonstrated enhanced liver injury to CCl₄ or allyl alcohol at doses that did not cause liver injury in unrestrained animals [63]. This suggests that "psychogenic stress" may enhance susceptibility to liver damage by hepatotoxicants and may be a predisposing factor to liver injury after drug administration [63]. The underlying mechanism is considered to be the result of increased hepatic KC activation, with subsequent release of soluble mediators that sensitize liver cells to hepatotoxicants [63]. Proinflammatory conditions can significantly alter the hepatic response to drugs as a result of mediators and cytokines released from inflammatory cells. [62]. Endotoxemia is an example of a proinflammatory condition in which bacterial LPS is released as a result of liver disease, gastrointestinal disease, or drug effects on the intestinal mucosa [62]. Release of massive amounts of LPS can lead to circulatory shock, multiorgan failure, and death, whereas less amounts of LPS

release can cause a clinically silent inflammatory condition associated with increased release of eicosanoids, tumor necrosis factor alpha (TNF- α), reactive oxygen species (ROS), or reactive nitrogen species (RNS) [62,64,65]. In rats, administration of nontoxic amounts of LPS induces a low level endotoxemia resulting in a mild noninjurious inflammatory state that can significantly increase susceptibility to hepatotoxicants [62]. Pretreatment of rats with the H₂ receptor antagonist ranitidine before administration of a nontoxic dose of LPS produces hepatotoxicity [44,62]. Idiosyncratic liver toxicity occurs in <0.1% of people taking ranitidine, and while most hepatic reactions are mild and reversible, extensive liver damage and death may occur [64]. Ranitidine hepatotoxicity is typical of an IDR, where the time of onset varies greatly relative to the initiation of treatment. However, unlike other drugs where rechallenge results in a shorter time of onset of adverse effects, rechallenge with ranitidine does not inevitably result in the recurrence of hepatotoxicity [64]. This suggests that a mechanism other than immune-mediated is involved. However, this hypothesis predicts a random time to onset rather than a typical time to onset of one to three months, and IDR very rarely occurs immediately on first exposure to a drug (see *Idiosyncratic Drug Reactions and the Potential Role of Metabolism* in Volume VI).

In terms of patient susceptibility to IDRs, there is currently little evidence of a genetic predisposition to most IDRs. Certain IDRs such as abacavir-induced hypersensitivity are linked to a specific gene (*HLA-B*5701*) and flucloxacillin-induced hepatotoxicity is linked to the same gene [34,66]. However, there does not appear to be one gene that is linked to all IDRs. The *HLA-B*1502* gene is thought to contribute to the pathogenesis of carbamazepine-induced SJS/TEN, and the genetic susceptibility to carbamazepine-induced cutaneous ADRs is phenotype specific [67]. Although a few associations with genetic polymorphism for metabolizing enzymes have been identified, most investigations into this association have been negative [16,68]. This suggests that differences in drug metabolism do not represent major risk factors in the pathobiology of IDRs [16]. Furthermore, population studies do not currently fully support a genetic predisposition to IDRs [34]. Whole genome single nucleotide polymorphism (SNP) profiling may provide additional insight in determining genetic predisposing factors for ADRs [15].

17.4 ROLE OF REACTIVE METABOLITES IN IDIOSYNCRATIC DRUG REACTIONS

Although the mechanism of most idiosyncratic reactions is unknown, several characteristics of idiosyncratic reactions are suggestive of involvement of the immune system [69]. These include a lag period of more than a week between starting the drug therapy and the development of toxicity, immediate recurrence of the idiosyncratic response on reexposure to the drug, lack of correlation between dose and risk of toxicity, and the presence of eosinophilia [70]. In some cases, antibodies have been found to support an “allergic” nature of certain idiosyncratic reactions [70]. However, the molecular weight of molecules that are antigenic is generally greater than 1000 Da, whereas most drugs are not this large [70,71]. This suggests that molecules must bind to proteins in order to be antigenic (i.e., hapten) [69]. It also appears that covalent binding is required for immunogenicity since other types of chemical interactions such as ionic and hydrophobic binding are insufficient [71,72]. Furthermore, it appears that most drugs do not directly react with proteins to form covalent bonds [70]. This

implies that metabolism of a drug is critical to forming a hapten. Most drugs are metabolized to reactive metabolites that can covalently bind to proteins, and there appears to be a good correlation between the quantity of reactive metabolite formed and the risk of developing an idiosyncratic reaction [69]. Since the structure of the metabolite–protein adduct is likely very different from the parent molecule, the antibodies induced by the adduct may not bind to the drug itself [70]. There are several examples of metabolism of drugs producing metabolites involved in idiosyncratic reactions, such as halothane, isoniazid, and sulfonamide [69,70,73]. The reactivity of the metabolic intermediates together with their occurrence in certain tissues and their localization within a specific subcellular fraction of those tissues may be significant in the manifestation of toxicity in target organs [74]. Many drugs are target-organ specific; for example, halothane is metabolized in the liver and the toxicity of halothane is manifested selectively in the liver. Other end organs such as the lung and skin may also be sites of metabolism. In addition, many drugs (e.g., procainamide, sulfonamides) may also be metabolized by leukocytes to reactive intermediates, which may then lead to other types of hypersensitivity reactions such as agranulocytosis, drug-induced lupus, or generalized idiosyncratic reactions [70,75,76]. Many drugs that possess arylamine, sulfhydryl, or other readily oxidizable moieties are particularly susceptible to oxidation by activated leukocytes to reactive intermediates [70]. However, since activation of leukocytes is a necessary condition for the development of a leukocyte-associated idiosyncratic reaction, this implies that concurrent conditions such as infection or unspecified inflammation may be contributing risk factors [70]. Consistent with this hypothesis, a higher incidence of idiosyncratic reactions has been observed with some drugs in association with certain viral infections [70].

17.5 ANIMAL MODELS OF IDIOSYNCRATIC DRUG REACTIONS

On the basis of the uncertainty of the various proposed mechanistic hypotheses for IDRs and the potential for overlap of mechanisms involved, identification of a single *in vitro* or *in vivo* model to enable prediction of IDR has been difficult at best. In fact, current hypotheses preclude the possibility of reproducing such reactions *in vitro* [16,27]. Therefore, biomedical research with animal models represents the most probable direction for exploring models of IDRs. Idiosyncratic reactions have been reported in pet animals (dogs and cats) by veterinarians and with low incidence as in humans [77–79]. Unfortunately, IDRs in animals are also idiosyncratic, rarely occurring in preclinical species used in drug development and therefore unpredictable in animals, thus further complicating this approach to understanding the mechanisms involved in IDRs [16,80]. Furthermore, for an animal model to truly represent the human condition in IDR, it must possess a similar mechanism as that in humans. Although all of these factors need to be taken into account, animal models still represent the best approach to studying IDRs and may provide some mechanistic clues for understanding the nature of IDRs in humans. Not knowing the precise mechanism for human IDRs poses a quandary to establishing a relative animal model. Even in cases where the pathophysiology of a disease is well characterized, the toxic response to a drug may be significantly altered under these circumstances, a situation that is not often investigated in preclinical toxicity testing in drug development [62]. Nevertheless, to date, several animal models for IDRs have been investigated, which hold some promise and can be categorized according to putative mechanism (Table 17.1).

∞ **TABLE 17.1 Animal Models of Idiosyncratic Drug Reactions**

	Toxic Reactive Metabolite	Mechanism of IDR	Animal Model
<i>Animal Models of Drug-Induced Hypersensitivity</i>			
Sulfonamide (antibacterial)	Hydroxylamine and nitroso derivatives	Immune mediated (genetic predisposition? immune status? and antidrug antibodies)	Dog
<i>Animal Models of Idiosyncratic Liver Toxicity</i>			
Halothane (anesthetic)	Trifluoroacetyl chloride	Immune mediated (TFA-protein-adduct antibodies)	Rat, guinea pig, mouse
Isoniazid (antitubercular drug)	Acyl carbocation and free radical	Immune mediated? (protein acylation)	Rat, rabbit
Ticrynafen (tienilic acid) (antihypertensive)	Thiophene epoxide	Immune mediated (Cyp protein adduct and anti-CYP450 antibodies)	Rat
Acetaminophen	<i>N</i> -acetyl- <i>p</i> -benzoquinone imine	Direct cytotoxicity with involvement of innate immune system	Rat, mouse
Mitochondrial superoxide heterozygote mouse model	Troglitazone: quinone; flutamide: quinone imine	Mitochondrial dysfunction with oxidant stress	Sod2 ^{+/-} knockout mouse
<i>Animal Models of Drug-Induced Autoimmunity</i>			
D-Penicillamine (antirheumatic)	(IDR attributed to chemically reactive parent drug)	Immune mediated (genetic predisposition? and antinuclear antibodies)	Rat, guinea pig
Propylthiouracil (antithyroid drug)	Sulfonic acid	Immune mediated (antinuclear and antimyeloperoxidase antibodies)	Cat
Procainamide (cardiovascular agent)	Hydroxylamine and nitroso metabolites	Immune mediated? (antinuclear antibodies to histone)	Rat, mouse
<i>Animal Models of Drug-Induced Skin Rash</i>			
Nevirapine (antiretroviral agent)	Benzyl sulfate	Immune mediated (genetic predisposition? T-cell involvement?)	Rat
<i>Animal Models of Hematotoxicity, Bone Marrow and/or Liver Toxicity</i>			
Amodiaquine (antimalarial)	Quinone imine	Immune mediated (protein adduct and antidrug antibodies)	Rat
Felbamate (anticonvulsant)	Atropaldehyde	Immune mediated? (protein adduct)	Rat

? indicate mechanisms of IDR that are postulated but unproven.

17.5.1 Sulfonamide-Induced Hypersensitivity

Sulfonamide hypersensitivity is well recognized in humans and is manifested as fever, dermatopathy (i.e., rash), lymphadenopathy, and, occasionally, liver, kidney, or bone marrow dysfunction (e.g., agranulocytosis, eosinophilia, thrombocytopenia, or aplastic anemia) [81]. Clinically, the incidence of sulfonamide hypersensitivity may vary from <3% to 65% depending on an individual's immune status, occurring with higher incidence in immunosuppressed patients (e.g., HIV-positive individuals) [82,83]. Sulfonamide hypersensitivity has been commonly described in various dog breeds and has been categorized as polyarthritis/fever, cutaneous drug eruptions, hepatotoxicity, and blood dyscrasias [84,85]. The onset of clinical signs in dogs following initiation of treatment may range from 5 to 36 days [85]. Giger *et al.* [86] were able to demonstrate that the polyarthritis, glomerulonephropathy, and focal retinitis observed in Doberman pinschers following administration of trimethoprim sulfadiazine was due to the sulfadiazine since the recurrence of the polyarthritis occurred with rechallenge of sulfadiazine alone but not with trimethoprim alone. The more rapid onset with rechallenge with sulfadiazine was consistent with an immune-mediated reaction. Additionally, hypersensitivity in dogs has been shown to be associated with antidrug, antimyeloperoxidase, and anti-cathepsin G antibodies [87,88]. It is thought that the immune reaction to sulfonamide is triggered by a reactive metabolite since sulfonamides are metabolized to hydroxylamines that may be further oxidized to nitroso derivatives, which in turn may form protein adducts, culminating in antibody- and/or cell-mediated immune responses [88]. A dog may be a very good mechanistic model for sulfonamide hypersensitivity in humans since this syndrome in dogs shares many similarities with that in humans. The metabolism of sulfonamides is similar in dogs and humans, and antidrug antibodies and drug-serum adducts have been identified in dogs and humans with sulfonamide hypersensitivity [87]. However, the low incidence of sulfonamide hypersensitivity in dogs and the ethical and practical difficulties of working with dogs preclude the utility of this animal model [27]. Unfortunately, a rodent model is not available for sulfonamide hypersensitivity.

17.5.2 Halothane-Induced Liver Toxicity

Halothane may cause severe idiosyncratic liver toxicity in humans, albeit at low incidence [89]. Halothane-induced hepatotoxicity in guinea pigs is attributed to oxidative biotransformation [90]. In rats, halothane was demonstrated to cause liver toxicity but only if the rats were first pretreated with phenobarbital and then exposed to halothane under hypoxic conditions [91]. Halothane-induced hepatotoxicity in rats was attributed to hypoxia in combination with enzyme induction, leading to free radical formation by a reductive or non-oxygen-dependent metabolic pathway [92]. Halothane-induced hepatotoxicity in humans has been linked to the formation of antibodies to a reactive metabolite, trifluoroacetyl (TFA) chloride, covalently bound to a hepatic protein [93,94]. Multiple exposures to halothane is recognized as a major risk factor and halothane-induced hepatotoxicity is often associated with autoantibodies (e.g., autoantibodies to CYP2E1) and sometimes eosinophilia [95,96]. Taken together, these observations are consistent with an immune-mediated mechanism in humans [27]. Drug-specific T cells are also believed to play a role in the mechanism of halothane-induced liver injury ("immunoallergic hepatitis"), and it is considered that the balance

between different subsets of T cells (i.e., T-helper (Th) cells and T suppressor cells) influences individual susceptibility and the extent of hepatic injury [97]. Thus, it is likely that the mechanism involved in halothane-induced hepatotoxicity in humans differs from that in rats because different metabolites are involved and the immune-mediated mechanism of the human idiosyncratic reaction is not apparent in the rat model [27].

In guinea pigs, halothane-induced hepatotoxicity is observed when coadministered with buthionine sulfoxide (to deplete GSH), resulting in death within 48–72 h after a single exposure to halothane, which is more consistent with a direct toxicity rather than an immune-mediated mechanism [98]. However, antibodies to TFA-albumin have been observed after a single exposure to halothane in guinea pigs, and subsequent exposure to halothane also results in anti-TFA antibodies, although hepatotoxicity was not significantly altered and anti-TFA antibody titers were similar to those of the initial response [99,100]. These findings may be indicative of immune tolerance, similar to that observed in patients [27]. A cellular immune response has also been demonstrated in guinea pigs following halothane exposure, although the relationship to liver toxicity is not certain [101–103]. Thus, the guinea pig model may be useful in providing insight into the humoral and cellular immune responses involved in the human halothane-induced idiosyncratic reaction [98].

Halothane also causes acute hepatotoxicity in mice. It apparently involves the innate immune system because it is associated with an increase in TNF- α , interleukin (IL)-1 β , IL-6, and IL-8 levels, as well as recruitment of neutrophils [104]. Furthermore, neutrophil depletion was protective. It was also found that IL-17 level was elevated in this model and depletion of IL-17 was protective [105]. Although IL-17 is the cytokine after which Th-17 cells were named, it is also produced by other cells and can even be elevated in acetaminophen-induced hepatotoxicity, which is unlikely to be mediated by Th-17 cells. The presence of CYP2E1 IgG₄ autoantibodies in patients with anesthetic drug-induced liver injury (DILI) suggests that IL-4 may be involved in immune-mediated halothane hepatotoxicity [106]. The involvement of IL-4 in many autoimmune disease models (e.g., autoimmune diabetes, experimental autoimmune encephalitis, collagen-induced arthritis) is well known, but its immunomodulatory role is complex and multifaceted and may follow pro- or anti-inflammatory pathways [107]. In comparison to IL-4^{-/-} knockout (KO) mice, wild-type (WT) Balb/c developed more hepatitis, TFA and S100 antibodies, and T-cell proliferation following TFA-S100 immunization (oxidative metabolism of halothane by CYP2E1 produces TFA hapten, which is covalently bound to S100 hepatic protein) [106]. In this mouse model of anesthetic DILI, suppression of regulatory responses (IL-10, IFN- γ , and possibly IL-6) to CYP2E1 autoantigen and promotion of proinflammatory responses (TNF- α , IL-1 β , or IL-6) to TFA hapten suggest that IL-4 may play a dual role in immune-mediated halothane hepatotoxicity [106,107]. The mouse model appears to be significantly different than classic halothane-induced hepatotoxicity in humans; however, it is likely that the mechanism of IDRs can be different in different individuals.

17.5.3 Isoniazid-Induced Liver Toxicity

Isoniazid is an antitubercular drug that has been associated with liver injury following prolonged usage [108]. It is proposed that the hepatotoxicity is caused by acetylation

of isoniazid followed by the hydrolysis of *N*-acetylisoniazid [3,109]. Acetylhydrazine has been identified as a metabolite of isoniazid in humans, and *in vitro* studies have shown that acetylhydrazine may be further oxidatively metabolized by microsomal enzymes to a reactive acylating species that covalently binds to tissue macromolecules [108]. Further support for the involvement of a metabolite of acetylhydrazine in hepatotoxicity is provided, in that only a small protective effect is observed with the rapid acetylator phenotype contrary to what would be expected if hepatotoxicity only involved direct oxidation of isoniazid to a reactive metabolite [70]. Studies in rats have demonstrated that a similar pathway is followed for isoniazid-induced hepatotoxicity; however, the toxicity in the animal model occurs acutely, whereas hepatotoxicity in humans is usually delayed for a month or more [70]. This suggests that this IDR may be immune-mediated, which is further supported by the effect being largely dose independent. In humans, isoniazid hepatotoxicity may be due to an immune response to a metabolite bound to a protein that is then recognized as foreign [70]. Antibodies to isoniazid have been demonstrated in humans exposed directly or indirectly to isoniazid [110–112]. Rabbits may provide an alternate model for isoniazid-induced hepatotoxicity, exhibiting many features similar to isoniazid toxicity in humans, including the need for repeated dosing, a slight delay in the onset of release of hepatic enzymes, variability in the severity of toxicity, and histopathologic findings of liver necrosis and steatosis [113]. Additionally, the acetylation rate in rabbits is a genetically determined polymorphic trait, and so, similar to humans, rabbits may be classified as “fast” or “slow” acetylators [113].

17.5.4 Ticrynafen-Induced Liver Toxicity

Ticrynafen (tienilic acid) is a diuretic with uricosuric activity and is indicated for the treatment of hypertension. Shortly after it was introduced to the market in the United States in 1979, it was quickly withdrawn after it was determined to be associated with severe hepatotoxicity [114]. Similar hepatotoxicity was not observed in nonclinical studies in animals [70]. The delay in onset of hepatotoxicity following initiation of treatment was suggestive of an immune-mediated idiosyncratic reaction [70]. Antibodies to a hepatic cytochrome P450 isoenzyme were detected in patients with ticrynafen-associated hepatotoxicity [115]. The CYP450 involved (CYP2C9 in humans, CYP2C11 in rats) appears to be responsible for oxidation of the thiophene ring of ticrynafen to a reactive metabolite (arene oxide), which is highly electrophilic and immediately reacts with the CYP450 molecule that formed it [70,116,117]. A reaction occurs leading to alkylation of a thiol group in the enzyme's active site. The reactive intermediate that inactivates the CYP2C9 is the thiophene epoxide as determined by HPLC/electrospray ionization mass spectrometric analysis [118]. The reactive metabolite of ticrynafen covalently binds to the enzyme, thus inhibiting the enzyme irreversibly. It is postulated that this altered protein is immunogenic, leading to antibody formation against this cytochrome [70]. Since the CYP450 that ticrynafen reacts with is one of the common genetically variable CYP450s, individuals who lack this isozymes are likely to be protected from ticrynafen toxicity. Much of our understanding of the metabolic pathways of ticrynafen is based on *in vitro* investigations. Until recently, the putative metabolites of ticrynafen involved in idiosyncratic hepatotoxicity had not been detected *in vivo* [114]. However, a GSH–tienilic acid adduct has been identified in the bile of rats administered ticrynafen.

Coadministration of tienilic acid and the GSH biosynthesis inhibitor L-buthionine-(*S*, *R*)-sulfoximine (BSO) resulted in increased serum alanine transaminase (ALT) and hepatic necrosis which could be prevented by the CYP-inhibitor, 1-aminobenzotriazole. Thus, electrophilic metabolites of ticrynafen from CYP-mediated bioactivation may contribute to ticrynafen-induced hepatotoxicity, particularly where GSH biosynthesis may be impaired by a mechanism that causes electrophilic or oxidative stresses on hepatocytes [114]. However, the association of anti-CYP2C9 antibodies with clinical toxicity suggests that the hepatotoxicity in humans is mediated by the adaptive immune system, although the toxicity may be cell mediated rather than being antibody mediated.

17.5.5 Acetaminophen-Induced Liver Toxicity

Hepatotoxicity attributed to acetaminophen is well recognized in man and animals [97,119,120]. Acetaminophen-induced hepatotoxicity is attributed to an electrophilic CYP450 reactive metabolite, *N*-acetyl-*p*-benzoquinone imine, which covalently binds to cellular macromolecules and depletes GSH, leading to hepatocellular damage [3,119,121]. Although the mechanism of acetaminophen-induced hepatotoxicity has been attributed to direct liver cytotoxicity, more recent investigations have shown that the immune system may play a role [121,122]. In rats, pretreatment with inhibitors of macrophage function, such as dextran sulfate or gadolinium chloride, reduced serum transaminase levels and prevented centrilobular liver necrosis compared to rats administered only acetaminophen [27,122]. This suggests that activated macrophages play a role in acetaminophen-induced hepatotoxicity through the release of proinflammatory mediators (e.g., nitric oxide, IL-1 β , and TNF- α) [122]. Similar results have been observed in mice pretreated with gadolinium chloride [123].

Treatment of mice with liposome-entrapped clodronate to deplete KCs (the major resident macrophage in the liver) before administration of acetaminophen led to more severe hepatic necrosis and significantly elevated transaminase levels compared to mice treated with acetaminophen alone, in contrast to the effects observed with gadolinium chloride pretreatment [123]. The basis for the different effects of gadolinium chloride and liposome-entrapped clodronate is unclear. However, this suggests that KCs have a protective function in acetaminophen-induced hepatotoxicity possibly through the elaboration of cytokines and other mediators that are hepatoprotective [27,123]. IL-10 expression was demonstrated to be decreased in KC-depleted mice, suggesting that KCs are an important source of IL-10 and that this cytokine may be involved in cytoprotection [123]. In addition, IL-10 KO mice (IL-10^{-/-}) depleted of KCs have been shown to be more susceptible to acetaminophen-induced hepatotoxicity than intact mice, suggesting that other factors may be involved [27,123]. Other types of KO mice, including IL-6^{-/-}, tumor necrosis factor receptor 1 (TNFR1^{-/-}), cyclooxygenase-2 (COX-2^{-/-}), are also being used to investigate other cytokines or mediators that may be involved in acetaminophen-induced liver toxicity [27,124,125]. Thus, the occurrence and severity of acetaminophen-induced liver injury are influenced by factors that affect upstream events (i.e., drug metabolism) and downstream events (i.e., immune response) [120]. Although acetaminophen-induced liver injury is not considered an “idiosyncratic drug reaction” per se, the study of KO mice may provide insights into immune-mediated mechanisms of IDRs involving other drugs [27].

17.5.6 Mitochondrial Superoxide Heterozygote Mouse Model

One hypothesis for the mechanism of hepatic IDRs is that they involve damage to mitochondria [126]. Boelsterli developed an animal model in which Sod2^{+/-} mice heterozygous deficient in mitochondrial superoxide dismutase (a clinically silent genetic deficiency in mitochondrial function; complete deficiency is lethal) were treated with troglitazone (a thiazolidinedione antidiabetic drug) or flutamide (a nonsteroidal antiandrogen drug) and developed a delayed-onset hepatotoxicity [42,43, 127–129]. This is a very attractive model because, unlike many models, the toxicity is delayed in onset, thereby mimicking clinical idiosyncratic hepatotoxicity [33]. However, in the case of the troglitazone experiments, the toxicity was relatively mild (a twofold increase in ALT levels) and other groups have been unable to reproduce the results [130]. One possible source of the difference in results is that in the Boelsterli study, troglitazone was dissolved in Solutol HS 15/water solution and administered by intraperitoneal injection, while in the Fujimoto study, it was administered by oral gavage. Solutol HS 15 has the potential to cause mitochondrial damage because it contains polyglycol esters of 12-hydroxystearic acid.

It is postulated that the underlying impairment of mitochondrial function in this model sensitizes hepatic mitochondria to an additional oxidant stress by drugs that target mitochondria, such as troglitazone and flutamide [42,43]. The mechanisms by which these drugs potentiate oxidant stress are as yet poorly understood. One possibility is that ROS are generated metabolically and the increased superoxide levels overwhelm the antioxidant defenses over time [127]. Metabolism of both troglitazone and flutamide produces reactive intermediates. The major CYP3A4-dependent metabolite of troglitazone in mice, rats, and humans is a quinone, and quinones may undergo redox cycling thereby causing oxidative stress [131–133]. Troglitazone is also an inducer of CYP3A4, which may further contribute to its toxicity by autoinduction and generation of reactive intermediates [132,133]. Metabolism of troglitazone at the thiazolidinedione ring (mediated largely by CYP3A) may result in the formation of thiol-reactive reactive intermediates and, subsequently, the formation of GSH conjugates, which may also add to oxidant stress [132,134,135]. It is also possible that formation of troglitazone phenoxy radicals by peroxidase/H₂O₂ demonstrated *in vitro* may deplete GSH and contribute to its prooxidant activity and hepatotoxicity [136]. Flutamide is also known to produce reactive metabolites from metabolism by CYP1A2, CYP3A4, and CYP2C19 and the carboxylesterase pathway [137]. Hepatic protein adducts (e.g., GSH conjugates, mercapturic acid conjugates) are formed from N-hydroxylation of flutamide metabolites, which is a proposed mechanism of flutamide-induced liver injury [137–143]. Aromatic hydroxylation of flutamide metabolites followed by oxidation results in the formation of a reactive quinone imine [140]. Additionally, flutamide contains a nitroaromatic group that can undergo redox cycling of the intermediates, which may enhance hepatocellular cytotoxicity by its detrimental effect on mitochondria [140,144,145]. Reduction of the nitro group to an amine is followed by oxidation to the diimine intermediate, which would be subject to subsequent nucleophilic attack by GSH at three unsubstituted positions of the aromatic ring to form GSH adducts [140,145]. Flutamide has also been shown to be an inducer of CYP1A2, which could also contribute to hepatotoxicity by further increasing oxidant stress [146]. More studies will be required to determine if this model represents the mechanism of idiosyncratic liver toxicity that occurs in humans.

17.5.7 D-Penicillamine-Induced Autoimmunity

D-Penicillamine (dimethyl cysteine) as a chelating agent has been shown to be efficacious in the treatment of Wilson's disease and cystinuria and also in the treatment of rheumatoid arthritis because of its immunologic properties [147]. However, its clinical use has been somewhat limited because of the occurrence of ADRs manifested by a broad range of autoimmune syndromes including lupuslike syndrome, pemphigus, myasthenia gravis, agranulocytosis, and rash [148–150]. In guinea pigs, chronic administration of D-penicillamine elicited electrophysiologic, serological, and histopathologic changes resembling experimental allergic myasthenia gravis and allergic myositis [147]. D-penicillamine causes similar autoimmune reactions in BN rats but not Lewis or Sprague-Dawley (SD) rats [151,152]. This suggests that genetic factors are important in D-penicillamine-induced ADRs in rats and that it is idiosyncratic in that it is strain specific [28]. The autoimmune syndrome in BN rats shares many features with that in humans, including antinuclear antibodies (ANAs) and immune complex deposition in the kidneys. Other manifestations include rash, weight loss, and, in cases of prolonged treatment, death [28,151]. Similar to humans, the onset of these effects in BN rats occurs after several weeks of treatment with D-penicillamine [16]. The mechanism of this idiosyncratic reaction in BN rats is clearly immune-mediated [153]. Although the incidence of immune disease does not increase at doses above 20 mg/day, tolerance is induced at lower doses. This tolerance can be transferred to naive rats by spleen cells or T cells from tolerized rats and is mediated by CD4⁺ regulatory T cells [154–156]. If animals are rechallenged with D-penicillamine after recovery, the onset of autoimmunity is similar to that observed following initial exposure [16]. Additionally, the onset, incidence, and severity of D-penicillamine-induced autoimmunity can be increased by administration of the Th1 cytokine inducer, poly I:C (a synthetic polymer of cytosine and inosine), which further supports an immune-mediated mechanism [157]. High throughput screening of hepatic mRNA using reverse transcriptase polymerase chain reaction (RT-PCR) has revealed that *Kid-1*, *sgk*, and *cinc* genes may be involved in determining sensitive and resistant animals [158]. Although reactive metabolites are postulated to play a role in IDRs, the mechanism of D-penicillamine-induced IDRs involves a chemically reactive drug rather than a reactive metabolite. It is still uncertain how D-penicillamine triggers the immune reaction, but it is postulated that D-penicillamine reacts with aldehydes to form an irreversible thiazolidine ring on APCs (i.e., macrophages), which become activated and may interact with T cells through formation of a reversible imine bond [159–161]. Transcriptome profiling of splenic macrophages obtained from BN rats following D-penicillamine treatment revealed upregulation of macrophage-activating cytokines (i.e., IFN- γ and GM-CSF [granulocyte-macrophage colony-stimulating factor]) and downregulation of IL-13 indicative of NK (natural killer) cell activation, as well as increased levels of TNF- α , IL-6, and IL-23 in a D-penicillamine-treated murine macrophage cell line (RAW264.7), further supporting the role of macrophages in the initiation of immune responses that, in some cases, may lead to generalized autoimmunity [162].

17.5.8 Propylthiouracil-Induced Autoimmunity

PTU therapy in humans for treatment of goiter has been associated with immune-mediated disease similar to lupus characterized by agranulocytosis, thrombocytopenia,

polyarthritis, vasculitis, hepatotoxicity, skin rashes, fever, and the development of ANAs but not hemolytic anemia [163–165]. Although efforts to induce immune-mediated diseases in animals have been largely unsuccessful, an animal model with clinical and serological characteristics of PTU-induced disease has been developed in cats [164]. Normal healthy cats administered 150 mg of PTU orally developed a disease syndrome characterized by lethargy, fever, weight loss, lymphadenopathy, Coombs' positive hemolytic anemia, a positive direct antiglobulin test (DAT), antimyeloperoxidase antibodies, and ANAs [28,164]. Onset of clinical signs varied from four to eight weeks of PTU administration, whereas the development of a positive DAT and/or ANAs occurred after three to eight weeks of treatment [164]. Clinical signs and serological changes resolved within two to four weeks of cessation of PTU administration [164]. On rechallenge, time to onset of PTU-induced autoimmunity was similar to the initial PTU-treatment period [27]. In humans and animals, drugs containing a sulfhydryl group have been associated with various immune-mediated diseases [151,164]. This hypothesis is supported by findings in the cat model, where resolution of both clinical and serological signs of disease occurred following the substitution of PTU administration with 150 mg of 6-propyluracil (PU), an analog of PTU that does not contain a sulfur moiety but has similar bioavailability [164]. Although antithyroid drugs do not bind to lymphocytes, the interaction of mononuclear phagocytes (i.e., macrophages) with lymphocytes is postulated to play a role in the development of PTU-induced immune-mediated disease [164]. Macrophages contain free sulfhydryl residues on their cell membranes that are essential to their function and the elaboration of various mediators [164]. PTU is metabolized by the myeloperoxidase (MPO)/H₂O₂/Cl⁻-system to reactive sulfonic acid metabolites [70]. Interaction of the reactive intermediates of sulfur-containing drugs, such as PTU, with sulfhydryl residues on macrophages may modulate the immune response through stimulation or suppression of lymphocyte proliferation, as well as promotion or suppression of immunoglobulin production, such as autoantibodies [164]. Consistent with this hypothesis, PTU is oxidized to reactive metabolites by the MPO system of macrophages, and PTU-induced autoimmunity in cats is associated with antimyeloperoxidase antibodies [166,167].

17.5.9 Procainamide-Induced Lupus

Procainamide is widely used as an antiarrhythmic drug. However, its chronic use has been associated with the development of an autoimmune disorder similar to lupus, agranulocytosis, and hepatotoxicity [32,70,168]. Lupus is characterized by the formation of antigen–antibody complexes and complement activation [70]. DNA is the principal antigen in antigen–antibody complexes in idiopathic lupus, whereas in procainamide-induced lupus, ANAs bind primarily to histone proteins rather than the DNA itself [70]. It is uncertain how procainamide antibodies form and bind to histone. Procainamide undergoes metabolic oxidation by liver microsomes to form reactive hydroxylamine, and nonenzymatically, it forms nitroso metabolites [169,170]. Nitroso-procainamide covalently binds histone and other proteins, whereas *N*-acetylprocainamide is not metabolized to a reactive metabolite and does not induce lupus [170,171]. The procainamide–histone protein if recognized as foreign could induce an immune reaction resulting in the production of ANAs [170]. Since procainamide metabolites are further metabolized in the liver, it is difficult to understand how systemic manifestations of procainamide-induced lupus occur. It has

been shown that activated mononuclear leukocytes and neutrophils generate H_2O_2 and MPO, which can metabolize procainamide to hydroxylamine [171,172]. Investigations of administration of procainamide to human neutrophils *in vitro* and rat tissues *in vitro* and *in vivo* confirmed the bioactivation of procainamide to reactive metabolites by activated neutrophils and subsequent covalent binding of reactive metabolites to the cell membrane of neutrophils where oxidation via the MPO system occurs [173]. Similarly, procainamide reactive metabolites may be formed and may bind to the cell surface of activated monocytes, which may influence antigen processing, a key function of monocytes [172]. Thus, the binding of reactive metabolites of procainamide to neutrophils and monocytes may be an initial step in triggering an immune response [171]. Antimyeloid cell antibodies have been identified in cases of procainamide-induced agranulocytosis [174]. Since most reactive metabolites have a short half-life, the formation of the reactive metabolites of procainamide in proximity to neutrophils in bone marrow and circulating monocytes provides a plausible mechanism for an idiosyncratic adverse reaction resulting in agranulocytosis and lupus through an immunologic mechanism [175].

Although an immune response manifested as a DHT reaction and a low titer of antibody to the drug was demonstrated in guinea pigs administered with procainamide in combination with complete Freund's adjuvant (CFA), attempts to develop an animal model of procainamide-induced lupus have generally been unsuccessful [176]. Administration of procainamide hydroxylamine intrathymically to C57BL/6 $\times$ DBA/2 F1 mice resulted in an initial and transient production of IgM antidenatured DNA antibodies, which was followed by a delayed and protracted IgG antichromatin antibody response [177]. Although the loss of IgG tolerance to chromatin in mice is consistent with findings in procainamide treatment in humans, the animals do not develop any clinical signs of autoimmunity, indicating a limited utility for this animal model [27,177]. Procainamide has also been shown to inhibit DNA methylation and induce reactivity to $CD4^+$ T cells, and therefore, this epigenetic effect appears to play an important role in the induction of lupus [178,179].

17.5.10 Nevirapine-Induced Skin Rash

Nevirapine is a nonnucleoside reverse transcriptase inhibitor (NNRTI) intended for the treatment of HIV-1 infections [180]. However, its use has been associated with a high incidence of idiosyncratic skin rash and liver toxicity, which may be life threatening [27,181]. At 400 mg/day, the incidence of skin rash can range from 17% to 48% depending on dosing regimen, with 0.3% of rashes considered severe, that is, SJS, SJS/TEN transition syndrome, or a syndrome of drug reaction with eosinophilia and systemic symptoms (DRESS) [180,182–185]. Sixteen percent of patients treated with nevirapine developed a skin rash, and of them, 65% developed the rash in less than six weeks following nevirapine treatment [182]. In clinical trials, 1.0% of nevirapine-treated patients developed clinical hepatitis, usually occurring within the first five weeks of treatment but delayed as late as 18 weeks in some cases [182,183].

Administration of nevirapine to BN rats and SD rats is also associated with skin rash but not liver toxicity [16,28]. However, Lewis rats are resistant to nevirapine-induced rash, which is consistent with the idiosyncrasy of the skin reactions and suggests that genetic factors may play a role in the development of skin lesions [27,28]. The similarity of the characteristics of nevirapine-induced skin rashes in rats and humans suggests

a common mechanistic pathway [27,180]. In rats, skin lesions occur two to three weeks after nevirapine administration; however, if administration is stopped followed by rechallenge after the rashes have resolved, then the reappearance of red ears occurs in <24 h and the rash is associated with more severe systemic manifestations than the original rash [186]. Histopathologically, the skin lesions are characterized by an inflammatory infiltrate of predominantly lymphocytic cells consisting largely of CD4⁺ and CD8⁺ T cells, as well as macrophages [187]. These findings provide strong evidence for an immune-mediated reaction. Depletion of CD4⁺ T cells, but not CD8⁺ T cells, was partially protective, and sensitivity can be transferred by isolated CD4⁺ T cells, but not CD8⁺ T cells, from sensitized to naive rats [180,188]. Furthermore, tolerance can be induced in BN rats by administration of low doses of nevirapine (50–75 mg/kg/day) followed by a higher dose (150 mg/kg/day), a dose typically associated with 100% incidence of rash [28,180]. The incidence and severity of nevirapine-induced skin rash appears to be related to the rat strain and gender [16,187]. The incidence of rash is higher in female BN rats than in male BN rats given the same dose, which appears to be related to kinetic factors; male BN rats metabolize nevirapine much more rapidly than female BN rats [28,187]. However, male BN rats develop skin rashes following administration of a cytochrome P450 inhibitor, aminobenzotriazole, which inhibits 2- and 3-hydroxylation but not 12-hydroxylation of nevirapine [28,189]. Mechanistically, the skin rash is related to 12-hydroxylation of nevirapine, rather than the parent drug, and it is postulated that the 12-hydroxy metabolite is converted by sulfation to a reactive quinone methide metabolite in the skin [16,180,189]. Since sulfotransferases are known to occur in skin, this provides a plausible explanation for the development of nevirapine-induced skin rashes [16,180]. Studies on the specificity of lymphocytes in nevirapine-treated BN rats have demonstrated that reactive metabolites may be responsible for initiation of an immune response but in addition, the immune response may be extended in that lymphocytes may also become reactive to the parent drug [190]. The BN rat appears to be a good model for the relatively mild maculopapular rashes that occur in some patients, which are likely mediated by CD4⁺ T cells, but the more severe rashes such as TEN are more likely mediated by CD8⁺ T cells [191].

17.5.11 Amodiaquine-Induced Liver Toxicity and Agranulocytosis

Amodiaquine, a 4-aminoquinoline, is an antimalarial drug [27,192]. The use of this drug has been restricted because of its association with hepatotoxicity and agranulocytosis [192]. Anti-amodiaquine IgG antibodies have been found in patients exhibiting adverse reactions to amodiaquine [193]. Amodiaquine is oxidized by liver microsomes and peroxidases to a reactive quinone imine, which can covalently bind to proteins [193,194]. In Wistar rats, administration of amodiaquine induces the production of specific IgG anti-amodiaquine antibodies after four days of treatment [195]. Antibody titers in rats were dose dependent and correlated with immunogenicity [195]. Activated polymorphonuclear cells have been shown to convert amodiaquine to reactive intermediates *in vitro* that can react with proteins, and therefore, it is plausible that a similar mechanism may occur *in vivo*, leading to an immunogenic response [195,196]. The specificity of the antibody to conjugates of amodiaquine quinone imine (via *p*-hydroxyanilino group) and cysteine residues in cellular proteins was determined by hapten inhibition [195]. At high doses, a significant decrease in peripheral white blood cell counts was observed in rats, which is suggestive of agranulocytosis, but it was not

reported if neutrophil counts were decreased, as would be expected in agranulocytosis [195]. Although ALT levels were increased in rats at high doses of amodiaquine, there was no evidence of hepatotoxicity histopathologically [195]. Peripheral white cell counts and ALT levels returned to normal within two weeks following discontinuation of treatment [195]. At lower doses of amodiaquine, there was an antibody response, but no alterations in peripheral white blood cell counts or ALT levels were observed [195]. Thus, amodiaquine is immunogenic at doses below which leukopenia or hepatotoxicity occurs [195]. Resolution of the adverse effects in rats may be indicative of immune tolerance [27]. The findings in amodiaquine-treated rats suggest that this may represent a suitable animal model of an immune-mediated idiosyncratic reaction in humans, involving a specific antibody response [28,195].

17.5.12 Felbamate-Induced Liver Toxicity and Aplastic Anemia

Felbamate (2-phenyl-1,3-propanediol dicarbamate) is an antiepileptic drug (AED) whose use has been restricted because of hepatotoxicity and aplastic anemia [11,197]. In contrast to humans, felbamate is essentially nontoxic in animals (i.e., rat, dog, and monkey) even at high doses [80]. Felbamate is metabolized by esterases to a monocarbamate, which is then oxidized by alcohol dehydrogenase to an aldehyde carbamate [11]. The aldehyde carbamate spontaneously gets converted to 2-phenylpropenal, an α,β -unsaturated aldehyde, also known as *atropaldehyde*, which is considered to be the reactive metabolite that may covalently bind to proteins and is responsible for the idiosyncratic toxicity of felbamate [11,198]. Although atropaldehyde, is found in rats, it has not been possible to develop an animal model for felbamate-related idiosyncratic toxicity [27]. The reason for the difference in toxicity between rats and humans may in part be related to the levels of atropaldehyde generated, which are lower in rats (~1%) than in humans (~6%) [199]. This may be attributed to the lower esterase activity in rats, which could reduce the amount of monocarbamate formed, in combination with enhanced CYP450 metabolism, increased detoxification by aldehyde dehydrogenase (which is present at higher levels in rats than in humans), and/or GSH conjugation of atropaldehyde [199]. Attempts to produce felbamate toxicity in rats through inhibition of protective metabolic pathways (i.e., aldehyde dehydrogenase, CYP450, GSH *S*-transferase, and glucuronosyltransferase) have failed possibly because of the inherent toxicity of the inhibitors [27]. In BN rats, coadministration of felbamate with poly(I:C) and ketoprofen, compounds known to increase the incidence, onset, and/or severity of the immune response in the penicillamine-treated rat model, also failed to produce liver or bone marrow toxicity, which is possibly related to immune tolerance [27,153,157]. Although felbamate has minimal effects on covalent-binding parameters, its effect on oxidative stress/reactive metabolite (OS/RM) gene expression in rat liver is quite pronounced, and this combination of assays may provide a useful alternative approach to screening compounds for the potential to form reactive metabolites that may lead to idiosyncratic toxicity [80].

17.6 PREDICTING IDIOSYNCRATIC DRUG REACTIONS

The unpredictable nature of IDRs makes them virtually impossible to prevent and difficult to study [16,70]. Identifying which patients may develop an idiosyncratic ADR

on the basis of the drug's chemical structure is also currently not possible [200]. Furthermore, despite years of extensive research, it is still impossible to predict the toxicologic potential of compounds that are metabolically activated [51]. Although the exact mechanism of IDRs is not known, reactive metabolites are considered to play a key mechanistic role [70]. Reactive metabolites can covalently bind to cellular proteins or oxidize thiol or amine groups that can result in tissue damage [200]. This can lead to cell death through apoptosis or necrosis, alteration of the immune system, or depletion of defense mechanisms such as GSH [200]. Advances in analytical methodology (e.g., mass spectrometry and NMR spectroscopy) have improved the detection of chemically reactive moieties, termed *toxicophores*, contained within the molecule, thereby assisting in the identification of potential targets of metabolism, which may form reactive metabolites [51,200]. Similarly, small-molecule trapping agents and covalent-binding studies using radiolabeled compounds have facilitated identification of reactive intermediates [51]. Although some animal models have been developed to investigate IDRs, these models suffer the same unpredictability for IDRs, as in humans [28]. Nevertheless, research with animal models has provided both insight into potential mechanisms that may be involved in IDRs and some control over certain variables (e.g., genetic, dietary, stressors) that can occur in human studies [201]. *In vitro* investigations have provided information on specific factors or pathways that may be involved in IDRs but lack the complexity of the numerous interactions and factors that occur *in vivo* [202]. To date, there are no methods sensitive enough to detect weakly sensitizing chemicals or robust enough for the purpose of routine screening [203].

Genetic linkage analyses have shown that multiple genes contribute to hypersensitivity [204]. However, prediction of hypersensitivity reactions is still hampered by both the complexity of the genetic mechanisms involved and our limited understanding of those mechanisms [204]. As cytokines are key regulators of immune responses, transgenic mouse models with overexpression or deletion of cytokine genes hold promise as animal models for investigation of the pathophysiological mechanisms of drug hypersensitivity [204]. Mice overexpressing Th2 cytokines (e.g., IL-4, IL-5, and IL-13) are of particular interest as models of hypersensitivity reactions [204].

17.7 CONCLUSIONS

There is circumstantial evidence that suggests that most idiosyncratic reactions are hypersensitivity reactions initiated by the formation of chemically reactive metabolites that bind to proteins and induce an immune-mediated response [70]. Toxicity may be limited to a target organ where the metabolism occurs and where consequently the largest concentrations of reactive metabolites may be present, such as liver and skin [160]. As a result of their reactivity, the response to reactive metabolites will typically occur in proximity to their formation [70]. For example, halothane is largely metabolized in the liver and halothane toxicity is selective for the liver. The role of activated leukocytes in the generation of reactive metabolites could explain IDRs in tissues other than the liver (e.g., agranulocytosis). Reactive metabolites binding to cellular proteins and thus making them appear "foreign" may also induce an immune reaction to "native" proteins, resulting in a more generalized drug-induced autoimmunity characterized by generation of autoantibodies [160]. Recent investigations continue to support the association of reactive metabolites and immune-mediated responses with IDRs, although

there may be exceptions (e.g., ximelagatran) [34]. Although many hypotheses have been proposed, the mechanisms involved in the occurrence of IDRs are complex and the development of appropriate animal models will be key to a better understanding of the basic underlying mechanisms involved in IDRs.

18.1 INTRODUCTION

In this chapter, several hypotheses that have been proposed to explain the basis of idiosyncratic, drug-induced liver injury (IDILI) reactions are reviewed briefly, with an emphasis on the inflammatory stress hypothesis. A short description of the inflammatory response is presented, and how it relates to recently developed animal models of idiosyncratic hepatotoxicity is described. The latter emphasizes sulindac (SLD), a nonsteroidal anti-inflammatory drug (NSAID) that has caused IDILI in human patients.

18.2 OVERVIEW OF IDIOSYNCRATIC, DRUG-INDUCED LIVER INJURY (IDILI)

Adverse drug reactions (ADRs) remain a major issue in affected patients and a huge challenge to health providers. The safety of a new compound is sometimes not well

understood until it has been on the market as a drug for several years. As a result, serious ADRs often emerge only after approval of a drug by the US Food and Drug Administration (US FDA). More than 10% of newly approved drugs from 1975 to 2000 in the United States either had to be withdrawn from the market or received a warning because of adverse reactions [1]. The liver, which plays an important role in the metabolism of drugs, is a frequent target of ADRs.

Hepatotoxic drug reactions are often categorized as one of two types: dose-related reactions (type A reactions) and idiosyncratic reactions (type B reactions). Type A reactions are dose-dependent and most likely occur in overdosed individuals. A typical example is an adverse reaction due to acetaminophen overdose [2,3]. Idiosyncratic ADRs differ from type A reactions in that they are unpredictable and occur in a minority (often a quite small percentage) of patients at therapeutic doses. The dose dependency in a population is obscure, although it is likely that within an individual the response is dose-related. IDILI typically does not occur by the same mechanisms that underlie the drug's pharmacological actions [4,5]. Many drugs have been associated with IDILI reactions (Table 18.1).

IDILI, which can result in permanent disability or death, has obvious importance to human health. In addition, these reactions are a major issue for the pharmaceutical

TABLE 18.1 Some Drugs Associated with IDILI in Humans

Acitretin	Lumiracoxib
Allopurinol	Minocycline
Amoxicillin/clavulanic acid	Naltrexone
Amiodarone	Nefazodone
Amitriptyline	Nevirapine
Azathioprine	Nimesulide
Benoxaprofen	Nitrofurantoin
Bosentan	Pemoline
Bromfenac	Penicillamine
Carbamazepine	Phenytoin
Chlorpromazine	Procainamide
Cyclosporine	Propylthiouracil
Dacarbazine	Quinidine
Dantrolene	Ranitidine
Diclofenac	Rifampicin
Dihydralazine	Stavudine
Disulfiram	Sulindac
Erythromycin	Tacrine
Estrogen	Tamoxifen
Felbamate	Terbinafine
Flutamide	Tienilic acid
Gemtuzumab	Tolcapone
Halothane	Troglitazone
Iproniazid	Trovaflaxacin
Isoniazid	Valproic acid
Ketoconazole	Ximelagatran
Labetalol	Zafirlukast
Leflunomide	Zileuton

industry because they lead to withdrawals and restrictions in the use of efficacious drugs. An example of a drug that caused idiosyncratic hepatotoxicity is troglitazone (TGZ), which was withdrawn from the market by the US FDA in 2000 [6]. TGZ is a peroxisome proliferator-activated receptor (PPAR)- γ agonist that was used to treat type 2 diabetes. The main reason for its withdrawal was that TGZ was associated with the development of acute liver failure [7], and it accounted for 10% of all idiosyncratic drug reactions between 1998 and 2001 [6]. Thus, although TGZ was beneficial in reducing insulin resistance, among 1.92 million patients who took the drug, 94 cases of liver failure were reported (89 acute, 5 chronic) [8]. A majority of these patients died, whereas others required liver transplants.

The risk for IDILI reactions is difficult to predict, and most idiosyncratic reactions are not discovered until a drug is on the market. That is in part because a mechanistic understanding of IDILI remains absent, and IDILI is generally not reproducible in traditional animal models used in preclinical safety evaluation. For example, oral administration of TGZ at large doses (60- to 120-fold larger than the therapeutic dose) to monkeys for 52 weeks did not increase levels of serum liver enzymes and had little gastrointestinal, hematologic, or hepatic effects [9]. The lack of preclinical animal models causes mechanisms of IDILI to remain poorly understood, so that appropriate action cannot be taken to prevent or treat these reactions.

18.3 PROPOSED EXPLANATIONS FOR IDILI

Although the mechanisms are still not fully understood, extensive studies on IDILI have been performed. Several hypotheses have been put forth to explain the modes of action and mechanisms of these responses. These hypotheses are described briefly, and the inflammatory stress hypothesis is described in more detail below.

18.3.1 Metabolic Polymorphism Hypothesis

The metabolic polymorphism hypothesis suggests that drug metabolites are responsible for IDILI and that susceptible patients metabolize the offending drug differently from the majority of the population. Some drugs are metabolized into electrophiles or free radicals, which can bind covalently to proteins and unsaturated fatty acids and/or can induce lipid peroxidation [10,11]. As a result, cell functions can be impaired and cytotoxicity initiated through cell death signaling pathways. Cytochrome P450s (CYPs) comprise a superfamily of enzymes that can transform drugs into reactive metabolites. Overexpression of CYPs in a fraction of patients can lead to excessive reactive metabolite formation and accumulation in the liver that can result in hepatotoxicity. Accordingly, polymorphisms that result in increased expression or activity of CYPs might be responsible for drug-induced hepatotoxicity in a fraction of patients. Alternatively, polymorphisms that result in diminished CYP activity could lead to hepatic accumulation of a drug that is toxic in its parent form.

TGZ is metabolized into its reactive metabolites by CYP3A4 [12]. CYP3A4-mediated oxidative cleavage of the thiazolidinedione ring generates a highly electrophilic metabolite, TGZ quinone, which covalently binds to cellular macromolecules [13]. This is supported by evidence that administration of TGZ to HepG2 cells transfected with CYP3A4 led to increased cytotoxicity [14]. On the other hand,

it has been suggested that TGZ quinone is less toxic to hepatocytes and HepG2 cells than TGZ itself [15]. Despite these results *in vitro*, the role of CYP3A4 in TGZ-induced toxicity *in vivo* is unclear.

Polymorphisms in enzymes responsible for conjugation reactions or in drug transport proteins also hold the potential to influence susceptibility to drug toxicity. Indeed, a variety of such polymorphisms have been associated with a number of drugs that cause IDILI [16]. For example, polymorphism of the *N*-acetyltransferase 2 gene has been identified as a susceptibility factor for IDILI from treatment with antituberculosis drugs such as isoniazid (slow acetylators are more susceptible) [17]. Polymorphisms of glutathione *S*-transferase M1 and T1 have also been associated with IDILI reactions from these drugs [18]. Variants of the genes for UDP-glucuronosyltransferase and for the multidrug resistance transport protein ABCC2 have been associated with diclofenac-induced IDILI [19]. It should be noted, however, that a causal link has not been established between these genetic polymorphisms and hepatotoxicity. It might be that for some drugs, metabolic polymorphisms play a permissive role but additional factors are required for the development of IDILI.

18.3.2 Hapten Hypothesis

The hapten hypothesis suggests that drugs, or more likely their reactive metabolites, form covalently bound adducts to cellular proteins [5,20]. The drug–protein adducts are recognized as nonself antigens by the immune system and are processed by antigen-presenting cells. The processed adducted peptides are presented to T cells, and this leads to the expansion of effector T and B cells that recognize the adducted peptides. On reexposure or continued exposure to the drug (i.e., drug challenge), an active immune response is elicited, which is associated with the production of specific antibodies to adducts and activation of cytotoxic T cells. This can result in a cascade of events that damage host tissue.

This hypothesis is supported by case reports in some patients with IDILI. Clinical characteristics accompanying some cases, such as skin rash and eosinophilia, are consistent with an adaptive immune response. In addition, antibodies have been detected in plasma after exposure to halothane, diclofenac, or TGZ, all of which cause IDILI in people [21–23]. However, evidence against this hypothesis has also accumulated for some drugs. Autoantibodies were present in only a fraction of the patients treated with diclofenac or halothane who developed liver damage and were detected in some patients, who did not experience hepatotoxicity [24,25]. Moreover, IDILI is induced in some patients after the first exposure to a drug [26,27], whereas a second exposure is needed to precipitate an adaptive immune response.

Several animal models of drug-induced adaptive immune response have been developed, including penicillamine-induced autoimmune syndrome and nevirapine-induced skin rash in rats [28,29]. Although antibodies against penicillin-modified proteins were present in rats treated with penicillin, liver injury was not induced in the animal model [30]. Similarly, liver damage was not observed in the nevirapine-induced skin rash model. Therefore, the results in animal models and human patients suggest that the autoantibodies are not necessarily pathogenic, and additional evidence supporting this hypothesis is needed.

18.3.3 Danger Hypothesis

The immune response induced by a foreign antigen can be weak in the absence of an adjuvant, which is a possible explanation for why an adaptive immune response induced by a drug itself is typically insufficient to cause liver injury [5]. The danger hypothesis was proposed as a modification of the adaptive immune hypothesis [31,32]. It suggests that necrosis or cell stress imposed by reactive drug metabolites provides a “danger signal” that activates macrophages, antigen-presenting cells, or other cells. The danger signals from stressed cells lead to upregulation of costimulatory molecules or production of cytokines that cause an enhanced antibody- or T-cell-mediated specific immune response. It is not clear what these danger signals are as they relate to drug-induced liver injury. Activation of the innate immune system, that is production of inflammatory mediators, was proposed to be a potential danger signal [4].

18.3.4 Mitochondrial Dysfunction Hypothesis

This hypothesis proposes that the mitochondria are targeted by drugs that cause idiosyncratic reactions, and the resulting mitochondrial damage is the underlying cause of some IDILI reactions. Mitochondria are critical players in mediating cell death and also common targets of xenobiotics [33]. Numerous drugs associated with IDILI, such as TGZ, tolcapone, nimesulide, and valproic acid, can cause mitochondrial dysfunction *in vitro* [34–38]. There is also clinical evidence associating IDILI reactions with mitochondrial dysfunction. For example, in one case report, mitochondrial swelling, loss of cristae, and reduced matrix density were observed in hepatocytes of a patient with tolcapone-induced liver injury [39].

An inherited mitochondrial dysfunction or mutation in mitochondrial DNA might make people more susceptible to drug-induced toxicity. In one case of valproate-induced liver injury, an inherited dysfunction of mitochondrial electron transport chain complexes was observed in the patient [40]. For many unrelated drugs, age is one of the risk factors for IDILI. This observation is of interest because mitochondrial DNA mutations increase with age [41].

Superoxide dismutase (SOD) eliminates the reactive oxygen species (ROS), superoxide anion, in mitochondria, and heterozygous SOD2 (SOD2^{+/-}) mice have a decreased ability to manage oxidative stress in the liver. These mice have been used to develop animal models of IDILI to test the mitochondrial dysfunction hypothesis. Nimesulide caused permeability transition of isolated mitochondria [42], and chronic treatment with this drug led to hepatocellular apoptosis in SOD2^{+/-} mice but not in wild-type mice [43]. TGZ, which injures isolated mitochondria and causes hepatocellular death *in vitro* [44], caused mild hepatocellular necrosis in SOD2^{+/-} mice, whereas no injury was observed in wild-type mice [45]. Similar results were obtained after administration of flutamide to these mice [46]. Accordingly, it is likely that mitochondrial toxicity occurs during IDILI, but whether it is a direct effect of drug/metabolite exposure or a distal event in a cascade that leads to cell death *in vivo* remains to be explored.

18.3.5 Failure to Adapt Hypothesis

Recent evidence suggests that it is not uncommon for drug treatment to lead to increases in plasma alanine aminotransferase (ALT) activity, a marker of hepatocellular damage

[47]. Despite continued exposure to the drug, ALT activity returns to normal in most patients [47]. This observation has given rise to the hypothesis that a fraction of patients who fail to adapt to this initial perturbation are those who progress to clinically significant liver injury. Mechanisms for this failure to adapt are unknown, and no animal models specifically designed to address this hypothesis have been established. Nonetheless, it is possible that factors involved in other hypotheses, such as metabolic polymorphisms and inflammatory stress, could underlie an inability to recover from the initial insult.

18.3.6 Multiple Determinant Hypothesis

This hypothesis states that IDILI is a result of the occurrence of multiple, critical, and discrete events or factors and that the probability of the occurrence of IDILI is the product of the probabilities of each event or factor [48]. This product would be small, thereby explaining the rare occurrence of these reactions. The critical events could include chemical properties of the drug, exposure (dosing regimen), environmental factors, and genetic factors. This hypothesis is consistent with other hypotheses described here, inasmuch as genetic polymorphisms, adaptive immune responses, mitochondrial toxicity, danger signals, and inflammation might each represent one event or factor that contributes to the overall probability of an IDILI response.

18.3.7 Inflammatory Stress Hypothesis

Inflammatory episodes are commonplace in humans and can be precipitated by infections, disease, or exposure to microbial products such as bacterial endotoxin. The principal biologically active component of endotoxin is lipopolysaccharide (LPS), a cell wall component of gram-negative bacteria. LPS is a potent inflammagen that at great enough doses can cause damage to several organs, including the liver [49]. Various conditions, including alcohol consumption, gastrointestinal distress, changes in diet, antibiotic treatment, and surgery, can increase LPS concentration in plasma of humans [50]. Such exposure may not be sufficient by itself to cause overt illness, but it might potentiate the toxicity of xenobiotics by activating inflammatory cells and cytokines. Previous studies have shown that inflammatory stress enhances the hepatotoxicity of numerous xenobiotic agents, for example, allyl alcohol, monocrotaline, and aflatoxin B1 [51–53].

The characteristics and effects of inflammation described above led to the inflammatory stress hypothesis. This hypothesis proposes that an inflammatory episode can render an individual susceptible to IDILI by decreasing the dose of the drug required for drug toxicity (Fig. 18.1) [54]. As modest inflammation is episodic in nature, IDILI arising from drug–inflammation interaction would be expected to have an inconsistent temporal relationship to drug exposure. Furthermore, because mild inflammatory responses can go unnoticed in humans, IDILI responses involving inflammation might not appear to be dependent on the dose of the drug. Accordingly, this hypothesis can provide an explanation for the characteristics of IDILI reactions.

There are many challenges to demonstrating that inflammatory stress contributes to IDILI. One is that by the time such reactions are suspected, a patient could have signs and symptoms of inflammation that have arisen as a consequence of initial

Figure 18.1 Illustration of the inflammatory stress hypothesis of IDILI. The normal, therapeutic dose lies to the left of the dose–response curve for toxicity in the absence of inflammatory stress. Inflammatory stress shifts the dose–response relationship for hepatotoxicity such that it intersects the normal, therapeutic dose, precipitating an idiosyncratic adverse reaction.

damage. Nonetheless, it is interesting that prodromal signs indicative of inflammation are common in people experiencing IDILI from some drugs [55,56]. Furthermore, many NSAIDs, which are often prescribed for inflammatory conditions, cause IDILI in humans.

Several rodent models of IDILI have been developed that support the inflammatory stress hypothesis. Specifically, diclofenac, SLD, halothane, chlorpromazine, ranitidine, and trovafloxacin, when administered at nonhepatotoxic doses, induced significant liver injury in rodents in the presence of a concurrent inflammatory stress [55–61]. The remainder of this chapter focuses on models of IDILI developed on the basis of this hypothesis. This begins with a brief description of inflammatory mediators that have been implicated in liver injury in drug–inflammation interaction models.

18.4 OVERVIEW OF THE INFLAMMATORY RESPONSE

Inflammation is a first-line defense mechanism by the innate immune system. It occurs in response to infection by pathogens, noninfectious disease, or tissue injury [62]. Tissue injury leads to activation of the innate immune response after trauma, which when severe can present as a systemic inflammatory response syndrome associated with multiple organ failure [63]. Inflammation is also associated with conditions such as anemia [64], Parkinson’s disease [65], diabetes [66], obesity [67,68], heart disease and other vasculopathies [69], and cancers [70,71]. Furthermore, inflammagens released into the circulation from periodontal disease are thought to be a risk factor for cardiovascular disease [72,73].

Inflammation is a complex response coordinated by various inflammatory cells and involves numerous soluble mediators (Fig. 18.2). Activation of toll-like receptors (TLRs) and the resultant intracellular signaling are involved in the initiation of the inflammatory response [74]. TLRs are expressed by inflammatory cells and recognize

Figure 18.2 Mediators of inflammation. In the liver, Kupffer cells, neutrophils, endothelial cells, hepatic parenchymal cells, and other cells such as NK/NKT (natural killer T) cells (not pictured) are involved in inflammatory responses. Inflammagens such as LPS bind to Toll-like receptors (TLRs) to activate cells, resulting in release of soluble mediators and activation of the complement cascade and coagulation system. Some of these changes are mediated by increased gene transcription. AA, arachidonic acid; NO, nitric oxide. (See color insert.)

specific structures conserved among microorganisms [75]. LPS binds to TLR4, resulting in intracellular signal transduction that leads to a cascade of inflammatory events [69]. Macrophages are the primary immune cells responding to LPS, although TLR4 is also expressed on the plasma membranes of hepatocytes, endothelial cells, and mast cells [76].

Neutrophils, macrophages, endothelial cells, epithelial cells, and platelets are all activated by inflammatory stimuli [54]. With the exception of platelets, activation results in increased expression of a variety of genes. Proteases and ROS are released by neutrophils and macrophages and can kill parenchymal cells directly. Proinflammatory cytokines, such as tumor necrosis factor- α (TNF), are produced and released by each of the cell types listed previously. These cytokines can either activate cell death signaling pathways or initiate other inflammatory events. The coagulation system as well as the complement system can also be activated as a result of inflammation. Some of these mediators are described in greater detail in subsequent sections.

18.4.1 Tumor Necrosis Factor- α (TNF)

TNF is a proinflammatory cytokine that is produced by many cell types, such as macrophages, mast cells, endothelial cells, and stellate cells, in response to LPS [77,78]. Kupffer cells are resident macrophages that exist in liver in close apposition to the luminal surface of endothelial cells in liver sinusoids [79], and they are the major macrophage population exposed to blood-borne inflammagens. After LPS binds to

TLR4, pro-TNF is produced by Kupffer cells as a result of activation of the NF- κ B (nuclear factor kappa B) signaling pathway. Pro-TNF is a 26-kDa membrane-bound precursor form that is not biologically active [80]. Tumor necrosis factor converting enzyme (TACE), a membrane-bound metalloprotease, recognizes a cleavable signal sequence on pro-TNF and mediates shedding of the active 17-kDa form of TNF from the cell membrane [81,82].

TNF exerts its biological effects through two plasma membrane receptors: tumor necrosis factor receptor 1 (TNF-R1) and tumor necrosis factor receptor 2 (TNF-R2). In a few cell types, for example, T cells, the binding of TNF to TNF-R2 leads to proliferation, NF- κ B activation, and cytokine production [83,84]. However, in most cells, TNF-R2 has no direct effect on signal transduction and plays an indirect role in TNF-R1 responses by delivering TNF to the lower affinity TNF-R1. The ligand-passing activity of TNF-R2 allows fine tuning of TNF-R1-mediated signal transduction.

TNF plays an important role in regulating liver homeostasis [82]. TNF-R1 activation leads to hepatocyte proliferation via the activation of NF- κ B, the initiation of mitogen-activated protein kinase (MAPK) cascades, or cell death. Whether TNF leads to cell survival or death is determined by NF- κ B [82]. NF- κ B plays a protective role against cell death by inducing the expression of several antiapoptotic genes, including caspase-8 inhibitor c-FLIPL, the Bcl-2 family members Bcl-xL and A1/Bfl-1, and X-linked inhibitor of apoptosis (XIAP) [85–87]. Moreover, prolonged activation of c-Jun N-terminal kinase (JNK), resulting from ROS production or TNF signaling, causes cell death [88], and NF- κ B indirectly downregulates TNF-induced JNK activation [89].

In addition to its role in cell death and survival, TNF regulates production of other inflammatory mediators. It positively controls production of a variety of cytokines and chemokines including interferon gamma (IFN- γ), interleukin 6 (IL-6), vascular endothelial growth factor (VEGF), monocyte chemotactic protein 1 (MCP-1), and macrophage inflammatory protein (MIP)-1 α [90]. TNF also promotes a procoagulant state by upregulating tissue factor, plasminogen activator inhibitor 1 (PAI-1), and platelet-activating factor and by downregulating tissue plasminogen activator [91]. Thus, TNF has multiple roles in inflammation and inflammation-mediated injury.

18.4.2 The Hemostatic System and Hypoxia

Vascular hemostasis is regulated by coagulation and fibrinolysis. The coagulation system is activated in many inflammatory diseases [92]. It can be activated through the extrinsic or the intrinsic pathway. In the extrinsic pathway, tissue factor is exposed to blood and forms a complex with factor VII, which activates factor X through the activation cascade. Factor X cleaves prothrombin into thrombin, which converts fibrinogen into fibrin monomers. Fibrin can cross-link to form fibrin clots in blood vessels [93]. This process is balanced by fibrinolysis, in which fibrin clots are degraded by plasmin [94]. Plasminogen activators (PAs) cleave plasminogen to active plasmin. PAs are inhibited by active PAI-1, which is synthesized by hepatocytes, endothelial cells, and platelets in response to TNF or inflammagens such as LPS [95,96]. Therefore, an increase in active PAI-1 can dampen the fibrinolytic system and thereby enhance fibrin deposition.

Fibrin deposition controls the magnitude and area of infection and by doing so plays a protective role against inflammagen exposure. However, detrimental effects can also occur when fibrin deposited in liver sinusoids impairs blood flow and causes

tissue hypoxia. Hypoxia activates numerous intracellular signaling pathways related to the transcription of hypoxia-responsive genes, mostly mediated by hypoxia-inducible factors. ROS that are produced after exposure to hypoxia lead to the mitochondrial permeability transition [97,98]. Energy deficit (loss of ATP) and inhibition of aerobic metabolism also result from the decrease of available oxygen. Physiological function is impaired, and liver damage can occur [99]. Hypoxia enhances LPS-induced liver damage *in vivo* [100] and potentiates the toxic effects of polymorphonuclear leukocyte (PMN)-derived proteases on hepatocytes *in vitro* [101].

Thrombin and PAI-1 are the two critical factors in regulating the hemostatic system and fibrin deposition, but they also play a role in activating inflammatory cells. Thrombin cleaves and activates G-protein-coupled receptors, including protease-activated receptor 1 (PAR-1), which significantly increases production of proinflammatory cytokines (TNF, IL-1, and IL-6) from target cells [102]. *In vitro*, PAI-1 potentiates LPS-induced neutrophil activation through a JNK-mediated pathway and by enhancing nuclear translocation of NF- κ B. The latter leads to the production of IL-1, TNF, and MIP-2 [103]. Studies *in vivo* also suggest that PAI-1 contributes to the production of TNF, IL-10, keratinocytes chemoattractant (KC), and MCP-1 [104].

18.4.3 Neutrophils (PMNs)

PMNs are abundant blood leukocytes that play an important role in the innate immune response. They protect tissues from pathogens but can also contribute to tissue injury in conditions such as ischemia-reperfusion and alcoholic hepatitis [105]. PMNs are involved in several models of drug-induced liver injury and in drug–LPS interaction models of idiosyncratic liver injury [57,105–108].

PMNs migrate from vessels into tissues and are primed and activated by systemic or local exposure to proinflammatory mediators. TNF, IL-1, or CXC chemokines (cytokine-induced neutrophil chemoattractant-1 (CINC-1), MIP-2) increase the expression of integrins on the surface of PMNs as well as intercellular adhesion molecule 1 (ICAM-1) and vascular cell adhesion molecule 1 (VCAM-1) on the surface of endothelial cells [109,110]. The binding of an adhesion molecule to its integrin receptor results in tight adherence of PMNs to endothelial cells, which is necessary for migration into tissue. Selectins are another type of adhesion molecule that is responsible for accumulation of PMNs in the vasculature of some tissues; however, in the liver, PMN accumulation in sinusoids can occur independently of selectins [111]. PMN migration from the vasculature and infiltration into the parenchyma is a prerequisite for neutrophil-induced cytotoxicity [109] and is mediated by several mechanisms. CXC chemokines as well as products released by dying cells, such as high mobility group box 1 (HMGB1), can instigate PMN migration [112,113]. Anti-HMGB1 antibody significantly reduced the production of proinflammatory cytokines and PMN infiltration in an ischemia-reperfusion model of liver injury [113]. Apoptotic cells might also trigger PMN migration [114]. It has been proposed that gaps in the sinusoidal endothelial cells may facilitate the direct contact of PMNs with altered membranes of apoptotic cells [114].

After PMNs cross the endothelial cell barrier, they localize close to hepatocytes and degranulate, leading to the release of proteases. They also produce ROS, including hydrogen peroxide and hypochlorous acid [115]. Both proteases and ROS contribute to liver injury in animal models [114]. Cathepsin G and elastase are two cytotoxic proteases released by activated PMNs. They are important mediators of

hepatic parenchymal cell killing *in vitro* [116], and inhibition of elastase protected against liver injury in drug–inflammation interaction models [106,108,136]. Besides a direct effect on hepatocytes, proteases released by PMNs can also contribute to fibrin deposition by activating PAI-1 [106].

18.4.4 Reactive Oxygen Species (ROS)

ROS comprise free radical and nonradical, reactive oxygen molecules. They include hydrogen peroxide, superoxide, and hydroxyl radical, and their reaction with cellular constituents can lead to the generation of other reactive species such as lipid free radicals and unsaturated aldehydes. ROS are produced by several sources within the cell. Mitochondria, in which the electron transport chain transfers electrons to oxygen, are a major source of ROS. It has been estimated that during normal cellular respiration about 2% of electrons escapes, and this leads to the production of superoxide anion [117]. As described in previous sections, TNF and hypoxia can increase ROS generation in a mitochondria-dependent manner. Another major source of ROS is nicotinamide adenine dinucleotide phosphate (NADPH) oxidase complex. This complex assembles on phagosomal, plasma, and granule membranes of cells, including activated PMNs, endothelial cells, and macrophages [115]. NADPH oxidase reduces oxygen to superoxide as it oxidizes NADPH [118]. In addition, many other enzymes, including xanthine oxidase, cyclooxygenases (COX), lipoxygenases, myeloperoxidases, hemoxygenases, monoamine oxidases, aldehyde oxidase, and CYPs, can produce ROS. However, the capacity of these enzymes to generate ROS is typically less robust than the mitochondrial electron chain complex or NADPH oxidase [119].

Excessive ROS can tilt the prooxidant–antioxidant balance within cells, causing oxidative stress. ROS can directly oxidize proteins and lipids, as well as nucleic acids, leading to cellular damage and dysfunction [119]. In addition, ROS can regulate the activities of numerous enzymes. For example, they inactivate JNK phosphatase, which leads to prolonged activation of JNK [88]. Activated JNK phosphorylates antiapoptotic Bcl-2 family proteins (Bcl-2, Bcl-xL) and inactivates them [120,121], thereby predisposing cells to apoptosis.

Oxidative stress plays a role in several models of liver injury. For example, it contributes to ischemia-reperfusion injury in mice [122], alcoholic liver disease [123], and the pathogenesis of inflammatory liver diseases [124]. Oxidative stress has also been proposed as a potential mechanism of NSAID-induced hepatotoxicity [125].

18.5 MODELS OF DRUG–INFLAMMATION INTERACTION

There are few animal models to study the mechanisms of drug-induced idiosyncratic hepatotoxicity. One reason for this is that idiosyncratic hepatotoxicity induced by drugs only occurs in a small fraction of animals, as it often does in humans. However, imposing a stress on animals can reveal the hepatotoxic effects of some drugs. According to the hypothesis introduced above, that inflammatory stress precipitates idiosyncratic drug toxicity, several animal models of IDILI based on drug–inflammation interaction have been developed. The focus of the next two sections of this chapter is on a model developed for SLD-induced hepatotoxicity.

18.5.1 IDILI from Sulindac (SLD)

SLD is a prodrug in the therapeutic class of NSAIDs. It was introduced into the market in 1978 to relieve pain, tenderness, swelling, and stiffness caused by osteoarthritis, rheumatoid arthritis, and ankylosing spondylitis. SLD has a half-life of 8 h, and the typical dose for human patients is 150–200 mg, twice per day. The bioavailability of SLD is more than 90%. It is absorbed rapidly on oral administration and reaches a peak concentration in human plasma in 2–4 h [126]. SLD and its metabolites are secreted into bile, undergo enterohepatic circulation, and are excreted in urine and feces [127].

Bioactivation of SLD to its active metabolite, SLD sulfide, is a reversible reaction. Methionine sulfoxide reductase in both liver and gut flora is the enzyme primarily responsible for reduction of SLD to SLD sulfide, and a flavin-containing monooxygenase catalyzes the reverse reaction [128]. This same flavin-containing monooxygenase converts SLD to SLD sulfone irreversibly (Fig. 18.3). SLD sulfide is responsible for the pharmacological activity to inhibit COX 1 and 2 [129], with subsequent reduction in synthesis of prostaglandins.

The use of SLD in the United States was associated with several hundred cases of hepatic injury in the period 1978–1986 [130]. The US FDA Arthritis Advisory Committee wrote “the potential for producing liver injury is a class characteristic of NSAIDs” [130,131]. The incidence of SLD-induced hepatotoxicity was about 1 in

Figure 18.3 Metabolism of sulindac. Sulindac (i.e., the parent drug, sulindac sulfoxide) is metabolized by methionine sulfoxide reductase (MSR) to its active metabolite, sulindac sulfide. The reverse reaction is catalyzed by flavin-containing monooxygenase (FMO). FMO also catalyzes conversion of sulindac to sulindac sulfone.

100,000 patient-years of NSAID use [132]. According to the analysis of cases reported to the US FDA, SLD-induced liver injury most often occurred within eight weeks of maintenance therapy, whereas about 20% of the reported reactions occurred later [130]. Females were more susceptible to SLD toxicity than males, and two-thirds of the patients were over 50 years of age. Clinical chemistry parameters identified hepatocellular, cholestatic, and mixed patterns of injury, and histopathologically, the pattern of SLD-associated liver injury was cholestatic or hepatocellular. In the cases of hepatocellular injury, the lesions were panacinar in most cases (eight out of nine). Portal inflammation and eosinophil infiltration were observed in a portion of patients.

Mechanisms of SLD-induced idiosyncratic liver injury are not well understood. Because clinical characteristics consistent with hypersensitivity were observed in some patients, it was proposed that hypersensitivity accounts for a significant proportion of SLD-induced liver injury. However, no direct evidence for this has been found. Mitochondrial injury has also been proposed as a mode of action. A variety of NSAIDs (e.g., nimesulide, diclofenac, and SLD) or their metabolites injure mitochondria of hepatocytes *in vitro* [34–38]. There is little evidence *in vivo* supporting this hypothesis, and an animal model of idiosyncratic liver injury from SLD based on this hypothesis has not emerged.

18.5.2 An Animal Model of SLD IDILI Based on the Inflammatory Stress Hypothesis

To develop a liver injury model of SLD–inflammation interaction, rats were given two administrations of SLD (p.o.) with a 16-h interval [58]. Half an hour before the second administration of SLD, a nonhepatotoxic dose of LPS was administered (i.v.) to rats. Rats treated only once with SLD and LPS did not develop liver injury consistently. However, as assessed from increases in the activity of ALT in serum, liver injury was evident by 8 h and was statistically significant by 12 h in rats given LPS and two administrations of SLD. Markers of biliary injury were also increased. Midzonal hepatocellular necrosis was observed histopathologically only in livers of rats cotreated with SLD (two administrations) and LPS (Fig. 18.4). These results suggested that SLD interacts with inflammatory stress induced by LPS to produce liver injury.

Mediators of inflammation, for example, some cytokines, can affect the expression of enzymes involved in drug metabolism. Inflammation is most often associated with reduced expression of drug-metabolizing enzymes, and this could contribute to IDILI responses by decreasing clearance of drugs or their toxic metabolites [133]. In rats treated with SLD, the concentrations of SLD and its metabolites, that is, SLD sulfone and SLD sulfide, in plasma and livers were decreased by LPS cotreatment [134]. In contrast, their concentrations in the gastrointestinal tract and feces were increased by LPS cotreatment, suggesting decreased absorption of the drug. Thus, hepatotoxicity seen in SLD/LPS-cotreated rats was not due to the enhanced uptake of the drug, increased bioactivation of SLD to its toxic metabolite, SLD sulfide, or increased accumulation of SLD sulfide in the liver.

Several mediators potentially involved in the pathogenesis were investigated. Hemostatic factors, including PAI-1 and thrombin, were elevated in the plasma by LPS, and this effect was magnified by SLD cotreatment [58]. As a result, significant fibrin deposition was observed in liver sinusoids of rats cotreated with SLD/LPS compared to those treated with SLD or LPS alone. Hypoxia occurred in the livers of rats treated

Figure 18.4 Histopathologic changes in liver of rats treated with SLD/LPS. Vehicle (Veh) or SLD was administered at -16 and 0 h, and Veh or LPS was given at -0.5 h. The liver was taken at 12 h, fixed, processed, and stained with hematoxylin and eosin. No necrosis was observed in liver sections from rats treated with Veh, LPS, or SLD only. In this liver section from a rat treated with SLD/LPS, a large area of hepatocellular necrosis can be seen. The lesion (demarcated by a dashed line) is characterized by hepatocytes with pyknotic nuclei and eosinophilic cytoplasm.

with SLD/LPS, presumably as a result of impaired blood flow due to microvascular occlusion by fibrin clots. The anticoagulant heparin attenuated fibrin deposition and hypoxia in the liver and protected against hepatocellular necrosis induced by SLD/LPS. Moreover, hypoxia increased SLD-mediated cytotoxicity in isolated hepatocytes [58]. These results suggested that the hemostatic system and tissue hypoxia resulting from fibrin deposition contributed to the pathogenesis.

As noted earlier, TNF is a central mediator of inflammation. In rats treated with SLD/LPS, the LPS-induced increase in plasma TNF concentration was enhanced by SLD [134]. TNF neutralization using etanercept decreased serum ALT activity in SLD/LPS-cotreated rats, demonstrating an important role for TNF in the development of liver injury.

SLD sulfide was more cytotoxic to HepG2 cells and primary rat hepatocytes than SLD itself [134]. However, *in vivo*, the amount of SLD sulfide produced was insufficient to cause liver injury by itself, and another factor arising from administration of LPS was required. A direct cytotoxic interaction between SLD sulfide and TNF was suggested by the observation that cell killing by SLD sulfide *in vitro* was synergistically enhanced by TNF [135]. However, additional events contribute to hepatotoxicity *in vivo*. LPS treatment led to PMN accumulation in the liver, and SLD enhanced this effect [136]. Interestingly, activation of the accumulated PMNs was only evident in the livers of rats cotreated with SLD/LPS. Thus, the drug–inflammation interaction was required for activation of these cells. Either antibody-induced depletion of PMNs or administration of a PMN protease inhibitor, eglin C, attenuated liver injury, indicating that toxic proteases released from activated PMNs participate in the pathogenesis [136]. *In vitro*, PMN elastase acted synergistically with hypoxia to kill hepatocytes [101], raising the possibility that this same interaction might contribute to SLD/LPS-induced liver injury in the rat model.

Additional evidence suggested complex interactions among inflammatory mediators involved in SLD/LPS-induced liver injury. For example, neutralization of TNF or PAI-1, both of which are important mediators in liver injury induced by SLD/LPS, decreased PMN activation but did not affect PMN numbers in the liver. On the other hand, neutralization of TNF had no effect on PAI-1 production, suggesting a lack of dependence on TNF for PAI-1 involvement in toxicity [136].

SLD/LPS cotreatment produced a unique gene expression profile in the liver compared to treatments with SLD alone or LPS alone [135]. Analysis of the genes specifically changed by SLD/LPS at a time before the onset of injury suggested that a pathway associated with oxidative stress was perturbed. The concentration of protein carbonyls in mitochondria, a marker of oxidative stress, was increased only in rats cotreated with SLD and LPS [135]. Antioxidants protected against liver injury induced by SLD/LPS in rats and reduced cytotoxicity caused by SLD sulfide and TNF interaction *in vitro* [135]. Furthermore, TNF enhanced the cytotoxicity of hydrogen peroxide in HepG2 cells, suggesting the possibility of TNF-ROS interaction *in vitro* and *in vivo*.

Results of these studies suggest a complex, liver-damaging cascade of inflammatory events that is summarized in Fig. 18.5. LPS stimulates accumulation of PMNs in the liver, release of TNF, and initiation of coagulation. SLD enhances each of these initial responses. Increased TNF concentrations lead to PMN activation and subsequent release of proteases that are necessary for hepatocellular killing. Enhanced activation of coagulation and inhibition of fibrinolysis result in fibrin deposition in the liver and hepatic hypoxia. Hypoxia increases SLD sulfide-mediated cytotoxicity and has the potential to augment cell killing by proteases. In addition, cotreatment with LPS and SLD causes oxidative stress, and evidence from *in vitro* studies suggests that TNF increases ROS-mediated cell killing. Accordingly, TNF, the hemostatic system,

Figure 18.5 Proposed mechanism of LPS/SLD interaction that leads to liver injury.

hypoxia, and PMNs, as well as ROS, play important roles in the pathogenesis of SLD/LPS-induced liver injury.

18.5.3 Commonalities and Differences Among Liver Injury Models of Drug–Inflammation Interaction

Evidence in animal models supporting the inflammatory stress hypothesis has been accumulating. In rodents, inflammation precipitates liver injury induced by several drugs associated with IDILI in humans. These drugs include SLD, diclofenac, trovafloxacin, halothane, ranitidine, and chlorpromazine [55,56,58–61,137]. The characteristics and mechanisms involved in the pathogenesis have been studied to various extents, and the results are summarized in Table 18.2 and recent reviews [138,139]. Some commonalities and differences are mentioned here.

Most models have been developed using LPS, a product of gram-negative bacteria, to induce inflammation. Other inflammatory stimuli have been used with similar results, however, suggesting that the effect is related generally to the inflammatory response rather than to LPS specifically. For example, a gram-positive stimulus (a peptidoglycan–lipoteichoic acid mixture) or the viral RNA mimetic (polyI:C) increased liver damage from trovafloxacin or halothane, respectively [108,140]. In the trovafloxacin/LPS model in mice, replacing LPS with TNF also resulted in liver injury, supporting the idea that TNF is an early and central mediator in these models [141]. The routes of drug administration are different among the models, suggesting that liver injury is not dependent on a specific route of drug administration. The SLD/LPS model is the only one explored thus far, in which the drug was administered twice; one dose of SLD failed to induce reproducible liver injury in rats. The durations between drug and inflammation administration needed to elicit a toxic response also vary among different models.

SLD, trovafloxacin, and ranitidine models have been relatively well investigated using LPS as an inflammatory stimulus. Enhanced TNF release, activation of the hemostatic system, and PMN accumulation in liver have been observed in all of these models. Neutralization or inhibition studies showed that each of these mediators is critical to the pathogenesis of liver injury induced by the interaction with LPS [58,61,90,101,104,106,134,136,142,143]. PMNs are also critical to liver injury in rats cotreated with LPS and diclofenac; [57] however, the role of PMNs in chlorpromazine-induced liver injury has not been tested. Taken together, these results suggest that TNF, hypoxia, and PMNs are important players shared by several models of liver injury from drug–inflammation interaction. The results also indicated that these mediators are not independent but interact with each other; however, their interactions differ somewhat among models.

Some mediators have been found to be critical in the pathogenesis in a single model but have not been tested in other models; for example, IFN- γ and IL-18 are both involved in trovafloxacin/LPS-induced liver injury [144]. Oxidative stress proved to play a role in SLD/LPS-induced liver injury [135]. The roles of these mediators in other models have not been investigated.

In summary, evidence is accumulating to support the hypothesis that inflammation precipitates or enhances drug-induced liver injury for drugs that cause IDILI in humans. TNF, the hemostatic system, and PMNs are involved in the pathogenesis of all the liver injury models of drug–inflammation interaction in which their roles have been tested.

TABLE 18.2 Characteristics and Underlying Mechanism of IDILI in Models Based on the Inflammatory Stress Hypothesis

Drug	SLD	DCLF	TVX	RAN	CPZ	HAL
Inflammagen	LPS	LPS	LPS ^a or PGN + LTA	LPS	LPS	PolyI:C ^a or LPS
Route of drug administration	p.o.	p.o.	i.p.	i.v.	i.p.	i.p.
Number of drug administrations	2	1	1	1	1	1
Time (h) drug was given relative to LPS	–15.5 and 0.5	2	–3	2	2	–6
Hours after the drug administration when liver injury was observed	12 after second SLD	6	12	6	24	15
Drug enhanced TNF production	Y		Y	Y		Y
TNF involved in pathogenesis	Y		Y	Y		Y
Hemostatic system activated	Y		Y	Y		
Fibrin deposition and hypoxia involved in pathogenesis	Y		Y	Y		
PMN accumulation	Y	Y	Y	Y	Y	
PMN activation	Y			Y		
PMNs involved in pathogenesis	Y	Y	Y	Y		
Injury is IFN/IL-18-dependent			Y			
ROS involved in pathogenesis	Y					
Hemostasis affected by TNF	N		Y	Y		
PMN accumulation increased by TNF	N		N	N		
PMN accumulation affected by hemostasis				N		
PAI-1 increased by TNF	N		Y	Y		
PMNs activated by PAI-1 and TNF	Y			Y		
Kupffer cells and NK cells involved						Y

Abbreviations: Y, the phenomenon or mechanism is observed in the model; N, the phenomenon or mechanism does not occur in the model. SLD, sulindac; DCLF, diclofenac; TVX, trovafloxacin; RAN, ranitidine; CPZ, chlorpromazine; HAL, halothane; PGN, peptidoglycan; LTA, lipoteichoic acid.

A blank entry means the feature has not been tested or reported (see text for references).

^aIndicates the inflammagen used in the mechanism studies.

The roles of oxidative stress or proinflammatory cytokines other than TNF as well as other potential mediators remain to be determined for models involving drugs besides trovafloxacin and SLD. Studies of drug–inflammation models have generally clarified several important mediators involved in the liver injury observed in these models using drugs that cause IDILI in humans. However, the mechanisms of drug–LPS interaction remain incompletely understood. For example, the cellular sources of inflammatory mediators important in these responses have not been identified, and exploration into the signaling pathways leading to liver injury has only just begun. Importantly, the

molecular target to which drug binds to initiate interaction with inflammatory pathways is unknown.

18.6 CONCLUSIONS

Idiosyncratic drug reactions resulting in liver injury remain a health concern and a major reason for loss of therapeutically useful drugs from the market. Despite their importance and years of study, the mechanisms by which IDILI arises are still not understood, and animal models that could aid in understanding and predicting these reactions have only recently begun to appear. Numerous hypotheses have emerged suggesting that the reactions might occur from polymorphisms in drug-metabolizing enzymes or transporters; from adaptive immune reactions to haptens formed by reactive metabolites; from mitochondrial dysfunction rendered injurious by drug exposure; from failure to adapt to modest, drug-induced injury; from the intersection of multiple genetic, environmental, and drug-related factors; or from an injury-precipitating interaction of the drug with an episode of inflammation. Of these theories, the inflammatory stress hypothesis has thus far led to the most robust animal models. Drug–LPS interaction models have revealed that several drugs can potentiate the activation of inflammatory cells and the generation of inflammatory mediators that act synergistically with the drug to cause hepatocellular necrosis and/or that precipitate a complex cascade of inflammatory events that results in liver injury. These events include but are probably not limited to cytokine release, inflammatory cell stimulation, and coagulation system activation. Despite progress in developing these as well as models based on other hypotheses, the ability to predict which drug candidates are likely to cause IDILI remains poor. Further development and refinement of animal models is likely to enhance understanding of IDILI pathogenesis, and this in turn should lead to *in vitro* and *in silico* models that will improve preclinical prediction and lead to the discovery of better biomarkers for IDILI and strategies to prevent it.

19.1 SUMMARY

Under conditions of innate immune system activation (i.e., inflammation), the functions of specific cytochrome P450 enzymes, other drug metabolizing enzymes (DMEs), and drug transporters (DTs) are altered in the liver, small intestine, lung, kidney, and central

nervous system (CNS). Many of these effects are primarily manifest at the transcriptional/RNA level, leading to corresponding changes in protein levels and function. This not only leads to altered drug and xenobiotic toxicity and action in diseased humans, but also has importance for disease therapy with biologic drugs that target inflammatory mediators or their receptors. Major roles for proinflammatory cytokines such as interleukin-6 (IL-6), IL-1 β , and tumor necrosis factor- α (TNF α) are inferred from the abilities of these agents to affect DMEs and DTs in cultured cells and *in vivo*, but the *in vivo* contributions of cytokines to regulation of these proteins in different inflammatory disease states is still poorly understood.

19.2 INTRODUCTION

As is elaborated in detail in the ensuing pages, inflammation and infection in humans or experimental animals are associated with changes in the expression and function of many DMEs and DTs. Especially for the DMEs, in the majority of cases these effects result in an impairment of their function (enzyme or transporter activity), although some proteins can be induced.

It will become evident that the great majority of information in this area comes from studies on the cytochrome P450 (P450) enzymes. However, research on the regulation of other DMEs and DTs is progressing, and will be summarized hereunder. The majority of studies in animals have been performed on acute models of infection or inflammation [e.g., the bacterial lipopolysaccharide (LPS) model]. In most cases where the time course has been studied, the effects are transitory and drug metabolism or disposition normalizes with the resolution of the inflammation. However, there is also the potential for long-lasting effects of disease, as observed for flavin monooxygenase (FMO)-3 that remains downregulated in the livers of mice treated with *Citrobacter rodentium* long after the infection and concomitant colonic inflammation have resolved [1].

19.2.1 Effect of Disease on Clinical Drug Therapy

Downregulation of hepatic DMEs consequent to activation of host defense (the innate immune system) can be expected to reduce the hepatic clearance of drugs that are eliminated by the specific enzymes affected, resulting in elevated plasma levels of drug and possible toxicity if doses are not adjusted. For example, an outbreak of influenza virus was associated with increased incidence of theophylline toxicity in asthmatic children, concomitant with a 67% increase in theophylline half-life (corresponding to approximately a 40% decrease in clearance) [2]. Even relatively modest effects like this clearly pose a risk of drug toxicity and indicate the need for dose adjustment, when the drug affected has a low therapeutic index (such as theophylline, warfarin, and cyclosporine). More recently, a 90% decline in hepatic activity of CYP2D6 in human immunodeficiency virus (HIV)-infected patients was reported [3], indicating the potential for much greater effects on drug clearance in humans.

Conversely, induction of DMEs due to inflammation or infection would be expected to cause elevated clearance and reduced plasma levels of affected drugs, possibly resulting in therapeutic inefficacy. For example, in a review of the literature on pharmacokinetics in HIV/AIDS (acquired immunodeficiency syndrome), Dickinson *et al.* [4] concluded that there was a general trend toward reduced plasma levels

of protease inhibitors (CYP3A4 substrates), especially azatanavir, in people with HIV/AIDS, although no single study showed any significant differences. This would imply the induction of CYP3A4 and/or P-glycoprotein (PGP), although this has not been demonstrated.

The consequences of DT regulation by inflammatory factors may be anticipated. Downregulation of efflux transporters would be expected to result in increased bioavailability and tissue accumulation of drugs, whereas the same effect on uptake transporters would be expected to result in reduced bioavailability and tissue concentrations of drug. The reverse would be true for induction of the transporters.

Overall, the information on the impact of disease on drug metabolism and disposition in humans is scanty, and much more research is needed. However, such studies are very difficult because rarely does the researcher have access to patients with untreated disease, and the ethical issues associated with withholding or delaying treatment are manifest.

19.2.2 Drug–Drug Interactions (DDIs)

Many, if not all, of the effects of inflammatory diseases on drug metabolism are thought to be due to the action of proinflammatory cytokines on hepatocytes and other cells. To date, TNF α , IL-1 β , IL-6, and interferons (IFNs) have been implicated as the most important. While TNF α , IL-1, or IL-6 are not clinically used drugs, IFN α , β , and γ are all used to treat various cancers and are capable of downregulating P450 expression in cell culture and in animals *in vivo*. Therefore, they have the potential to interact with other medications. However, effects reported on drug metabolism in humans are inconsistent [5].

19.2.3 Drug-Disease-Drug Interactions (DDDI)

The recent advent of the so-called biologic drugs targeting proinflammatory cytokines or their receptors (Table 19.1) has resulted in a new type of drug–drug interaction (DDI) that is disease dependent, which we will call drug-disease-drug interaction (DDDI). Originally, it was thought that biologic drugs did not pose a risk for interactions with small molecule drugs, because the biologics are metabolized by completely different enzymes, and do not inhibit or induce DMEs. However, the results from two animal studies in which the downregulations of hepatic CYP3A enzymes were reversed by a polyclonal antibody to IL-6 [6] or by infliximab, a monoclonal antibody to TNF α marketed for the treatment of arthritis and other autoimmune diseases [7], demonstrated the possibility for disease-dependent biologic-small molecule interactions in humans. Recently, the Food and Drug Administration (FDA) approved a humanized monoclonal antibody to the IL6 receptor, tocilizumab, for the treatment of rheumatoid arthritis. The report of the FDA's Arthritis Committee notes that plasma levels of simvastatin (a CYP3A4 substrate) and omeprazole (a CYP2C19 substrate) were reduced in patients treated with tocilizumab, consistent with the ability of IL-6 to downregulate these P450s in primary human hepatocyte cultures [8]. Thus, biologics can reduce the therapeutic efficacy of small molecule drugs, by relieving the inflammatory downregulation of the enzymes involved in their clearance.

The extent of DDDIs is only beginning to be understood. When a drug neutralizes a cytokine that can directly regulate DMEs in the hepatocyte, a DDDI of the type described might reasonably be expected. However, other cytokines might act

TABLE 19.1 Biologic Drugs Targeted to Inflammatory Diseases

Drug	Target	Diseases/Indications
Adalimumab	TNF α	Rheumatoid arthritis
Certolizumab-pegol	TNF α	Crohn's disease
Etanercept	TNF α	Rheumatoid arthritis
Infliximab	TNF α	Rheumatoid arthritis, Crohn's disease
Golimumab	TNF α	Rheumatoid arthritis, psoriatic arthritis, ankylosing spondylitis
Canakinumab	IL-1 β	Cryopyrin-associated periodic syndromes
Rilonacept	IL-1 β	Cryopyrin-associated periodic syndromes
Anakinra	IL-1 receptor	Rheumatoid arthritis
Daclizumab	IL-2 receptor	Acute organ rejection, asthma, multiple sclerosis, autoimmune
Basiliximab	IL-2 receptor	Acute organ rejection
Tocilizumab	IL-6 receptor	Rheumatoid arthritis
Ustekinumab	IL-12 and IL-23	Psoriasis
Abatacept	B7, T-cell comodulator	Rheumatoid arthritis

The above drugs are monoclonal antibodies or Fab fragments except anakinra, which is a receptor antagonist; etanercept, which is a cytokine receptor fragment; and abatacept and rilonacept, which are fusion proteins.

redundantly with the one targeted by the biologic, such that no effect would have been seen. On the other hand, it is possible that any drug that resolves inflammation, regardless of its mechanism, has the potential to cause a DDDI by reducing production of the cytokines that act directly on the liver. It remains to be seen whether well-characterized nonbiologic drugs such as nonsteroidal anti-inflammatories might be involved in DDDIs.

19.3 THE INNATE IMMUNE SYSTEM AND ITS ACTIVATION IN INFLAMMATION AND INFECTION

19.3.1 Cellular and Molecular Aspects of the Innate Immune System

Mammals and other host organisms deal with invading organisms via the two branches of the immune system, that is, the innate and the adaptive immune system [9]. The innate immune system has developed to survey the plasma and tissues for signs of foreign organism invasion, and to respond rapidly to eliminate the danger. The adaptive immune system mounts a slower but more specific response, designed to remember the molecular characteristics of a pathogen or toxin and thus enable the host to respond rapidly to a subsequent infection weeks to years later. Cells and molecules associated primarily with innate immunity have been implicated in the modulation of drug metabolism and transport, and therefore we will concentrate on the innate arm of the immune system.

Inflammation is caused by the response of the innate immune system to invading organisms or to tissue damage. It can be thought of as an adaptive homeostatic mechanism that becomes detrimental if inappropriately stimulated or dysregulated [10]. The cellular response of the innate immune system to infection or the presence of damaging toxins is primarily mediated by granulocytic leukocytes of the myeloid

lineage: monocytes, macrophages, neutrophils, mast cells, basophils, and eosinophils [9]. Natural killer (NK) cells, a type of T cell, also participate. The innate immune system is activated by invading pathogens via several families of proteins, called *pattern-recognition receptors*, which recognize structural motifs common to many invading pathogens or the molecules they secrete [11]. These pathogen-associated molecular patterns (PAMPs), described in detail in the ensuing section, are characteristics of molecules such as LPS, double-stranded viral RNA, and bacterial muramyl dipeptide.

The pattern-recognition receptors are expressed primarily in macrophages, but also in monocytes and neutrophils as well as in fixed tissue cells such as epithelial cells and keratinocytes [9]. Engagement of PAMPs with their receptors initiates specific signaling pathways in the cells, which result in the secretion of cytokines such as $\text{TNF}\alpha$, IL-1, IL-6, and $\text{IFN}\gamma$ to initiate the inflammatory response. $\text{TNF}\alpha$ and IL-1 are so-called proinflammatory cytokines, whereas IL-6 can be either pro- or anti-inflammatory. These initiator cytokines then activate other immune and nonimmune cells to produce additional cytokines and prostanoids, as well as chemokines (chemotactic cytokines) such as macrophage inflammatory protein-1 α (MIP-1 α , chemotactic for neutrophils and NK cells) monocyte chemoattractant protein-1 (MCP-1, chemotactic for monocytes and basophils), and IL-8 (chemotactic for neutrophils). Chemokines induce the expression of adhesion molecules on host cells so that effector cells such as neutrophils and NK cells, recruited to the site of injury by the chemokines, attach to the host cells. The identities of the chemokines induced, and thus the immune cells recruited, depends on the initial cytokine pattern which in turn depends on the initiating signal and the tissue(s) in which they occur [12].

Of special interest for drug disposition are the specialized macrophages of the liver, Kupffer cells (KCs), which represent an estimated 80–90% of the fixed macrophages in the body [13]. KCs are found in the sinusoidal lumen, where they are well positioned to detect bacteria, their toxins, and breakdown products absorbed from the gastrointestinal tract. When activated by bacterial endotoxin or by complement, KCs release $\text{TNF}\alpha$, IL-1, and IL-6 as well as nitric oxide, superoxide (from NADPH oxidase), prostaglandins, and thromboxanes. Therefore, it should be apparent that the local concentrations of these agents in the vicinity of the hepatocytes is likely to be much greater during inflammation caused by, for example, the injection of LPS than during inflammation elicited at a distant anatomical site. In the latter case, regulation of the hepatocytes will occur via circulating cytokines.

19.3.2 Pattern-Recognition Receptors

The best-understood family of pattern-recognition receptors is the family of integral membrane glycoproteins called *toll-like receptors* (TLRs) [11]. TLRs 1–9 are common to humans and mice, whereas the additional species-specific TLRs (TLR10 in humans and TLRs 11–13 in mice) are of unknown function. The TLRs recognize PAMPs associated with bacterial, fungal, and viral organisms (Table 19.2) [11]. TLR4, the best-characterized and prototypic TLR, was discovered as the gene whose mutation rendered mice (HeJ strain) insensitive to LPS. However, binding of LPS to TLR4 absolutely requires the presence of a soluble accessory protein MD-2 [14]. CD14 is another TLR4 accessory protein that sensitizes cells to LPS by facilitating ligand transfer to the receptor complexes and/or directing these complexes to signaling centers such as lipid rafts [14]. There is recent evidence that CD14 may also fulfill similar functions with

TABLE 19.2 Characteristics of the Toll-Like Receptors

TLR	Ligands	Signaling Pathways	Cellular Context	Hepatic Expression
1	Triacyl lipoprotein	MyD88/TIRAP	PM	SE KC SC

4	LPS	MyD88/TIRAP TRIF/TRAM	PM	H SE KC SC
5	Flagellin	MyD88/TIRAP	PM	SE KC SC
6	Diacyl lipoprotein Zymosan	MyD88/TIRAP	PM	SE KC SC
7	ss RNA, siRNA	MyD88/TIRAP	Endosomes	H
8	ss RNA	MyD88/TIRAP	Endosomes	SE KC SC
9	Unmethylated CpG-DNA	MyD88/TIRAP	Endosomes	SE KC SC

Abbreviations: PM, plasma membrane; H, hepatocytes; SE, sinusoidal endothelial cells; KC, Kupffer cells; SC, stellate cells.

TLR2 and other TLRs. For TLR4, CD14 also directs whether the responses will be via the MyD88/Mal or TRIF-TRAM (TIR-domain-containing adapter-inducing interferon- β /TRIF-related adaptor molecule) pathways (see below), this being dependent on the ligand [14].

While most TLRs homodimerize in response to ligand binding to initiate signaling, TLR2 heterodimerizes with either TLR1 or TLR6 to recognize bacterial, mycobacterial, and fungal products. Thus, TLR1/2 recognizes triacyl lipopeptides produced by gram-positive bacteria and mycobacteria, and TLR1/6 recognizes diacyl lipopeptides and fungal zymosan. TLR5 recognizes flagellin from flagellated bacteria.

TLRs 1, 2, 4, 5, and 6 are expressed on cell membranes, but TLRs 3, 7, 8, and 9 are found in intracellular membranes where they recognize PAMPs associated with intracellular pathogens. TLR3 recognizes double-stranded viral RNA, and is the receptor for the commonly used synthetic agonist polyI:rC. TLRs 7 and 8 recognize single-stranded viral RNA, and TLR9 distinguishes unmethylated CpG motifs associated with DNA from viral and bacterial pathogens.

The TLRs (mainly 2 and 4) also recognize damage-associated molecular patterns (DAMPs) on host molecules such as heat shock proteins and hemin, so that inflammation consequent to different types of tissue or cellular damage is also dependent on TLR2 or TLR4. There is some debate as to whether DAMPs themselves activate TLRs, or if they act by sensitizing cells to low levels of PAMPs [15].

Upon ligand binding, the TLRs dimerize to initiate signal transduction through two pairs of adaptor molecules: MyD88 and Mal/TIRAP (toll-interleukin 1 receptor (TIR) domain containing adaptor protein); or TRIF and TRAM (Fig. 19.1). However, only TLRs 2 and 4 need Mal/TIRAP or TRAM (Fig. 19.1). Both pathways result in the activation of NF- κ B, a transcription factor that is a master regulator of inflammatory gene expression, as well as activation of MAP (Mitogen Activated Protein) kinases that can regulate other transcription factors such as AP-1. Among the many targets of NF- κ B are proinflammatory cytokine genes such as IL-1, TNF, and IL-6, and also several hepatic acute-phase genes. Signal transduction via TRIF/TRAM results in the activation of transcription factors IRF3 and IRF7, causing the induction of IFNs α and β , which have antiviral activities. Activation of NF- κ B and MAP kinase (MAPK)

activation through the two adaptor molecules may be kinetically different and also cell-type dependent. Thus, the result of activation of a given TLR in two different cell types can be different [16].

While TLRs 1, 5, 6, 8, and 9 have not been reported on hepatocytes, they are all expressed in liver nonparenchymal cells (Table 19.2). Moreover, agonists of all TLRs evoked $\text{TNF}\alpha$ and IL-6 release by KCs, except for TLR5 that only evoked IL-6 release [16]. TLR3 and TLR4 agonists stimulated $\text{IFN}\beta$ release from KC as well. Liver sinusoidal epithelial cells released $\text{TNF}\alpha$ in response to TLR2, 3, 4, and 8 activation; and IL-6 in response to TLR3 or 4 activation [16]. Similarly, stellate cells express mRNAs for all nine TLRs, especially when activated [17]. Thus, any TLR agonist has the potential to affect hepatocyte DME and DT expression either directly or indirectly.

The roles of TLRs in regulation of DMEs and DTs have been explored to a limited extent. Perhaps not surprisingly, the downregulation of P450 enzymes [18–20] as well as of UDP-glucuronosyltransferase 1a1 (UGT1A1) [19] and the uptake transporter Oatp4 [21] in the LPS model of inflammation requires a functioning TLR4. On the other hand, the regulation of hepatic P450 enzymes in the liver during intestinal infection with *C. rodentium* is independent of TLR4 [20]. This demonstrates that gram-negative bacterial infection can influence hepatic gene expression via different mechanisms.

A second family of pattern-recognition receptors is the NLR (nucleotide-binding, leucine-rich repeat-containing) family, of which there are more than 20 in humans [22]. These intracellular sensors detect PAMPs such as muramyl dipeptide, LPS, flagellin, and bacterial or viral RNA, as well as DAMPs such as uric acid crystals, exhibiting significant overlap with TLR ligands. Ligand binding of NLRs results in

nucleotide-dependent activation of a large protein complex called the *inflammasome*, that in turn results in cleavage of procaspase-1 [22]. Active caspase-1 then cleaves pro-IL-1 and pro-IL-18 to their active forms, initiating an inflammatory response. NLR ligand binding can also mediate the activation of NF- κ B and MAP kinase pathways, which further stimulate the production of inflammatory cytokines, antimicrobial peptides, and reactive oxygen species [23]. In addition, NLR activation can be associated with both caspase-1-dependent and -independent cell death (specialized mechanisms of necrosis). This denies intracellular pathogens a cell in which to replicate, and also results in release of cellular components that can stimulate inflammation via TLRs [22].

The potential roles of NLRs and the inflammasome in regulation of DMEs during infection and inflammation are unknown. Mouse hepatocytes express the NLRs NOD1 and NOD2 and respond to NOD1 ligands with the activation of NF- κ B and MAP kinases [24]. Hepatic sinusoidal endothelial cells are capable of mounting an Nalp3 inflammasome response in response to DNA from apoptotic hepatocytes [25]. The potential for NLR involvement in DME regulation will be an important area of future research.

19.3.3 The Acute-Phase Response and the Liver

The acute reaction of the body to infection or tissue injury is termed the *acute-phase response* (APR), which encompasses all of the cellular and molecular events described above as well as the inflammatory symptoms of fever, redness, swelling, and pain that accompany them. The hepatic component of the APR includes the increased synthesis and secretion of a battery of proteins called *acute-phase proteins* (APPs) or *acute-phase reactants* [26,27] within a few hours of the initiating stimulus, and the reduced synthesis of other hepatic proteins called *negative APPs* (such as albumin). Thus, the many DMEs and DTs that are downregulated in inflammation can be considered to be negative APPs. APP synthesis is regulated largely by IL-1, TNF α , and IL-6, with IL-6 playing the dominant role [26]. In addition to acting directly on hepatocytes, however, IL-1 and TNF α can also stimulate KCs to release IL-6, affecting APP synthesis indirectly [27].

During chronic inflammation, serum levels of APPs are often elevated and are used as markers of inflammatory burden in humans. Because their expression and secretion integrate multiple upstream inflammatory signals including proinflammatory cytokines, APP levels tend not to fluctuate as much as those of the cytokines which are relatively short-lived [28]. Thus, serum APPs are being used to assess human health and predict the outcomes of some diseases including cancer [28].

19.4 CONSIDERATIONS FOR PREDICTING THE EFFECTS OF INFLAMMATION ON DRUG DISPOSITION AND DRUG-DISEASE-DRUG INTERACTIONS

The ultimate goal of research in this area is to develop biomarkers and decision-making tools that will allow prediction of changes in drug metabolism and disposition in an individual or a population due to a specific disease, and the prediction or exclusion of DDIs in people treated with anti-inflammatory biologic drugs. This would allow physicians to prescribe safer and more efficacious drug regimens for their patients, and also facilitate the drug development process. To achieve this goal, we must fully understand the multiple factors that can alter drug metabolism during inflammation and infection, and also the mechanisms by which these effects are achieved.

19.4.1 Roles of Cytokines and Other Mediators

Proinflammatory cytokines such as $\text{TNF}\alpha$ and IL-6 are capable of potent regulation of DMEs and DTs in hepatocytes and some other cell types, with a degree of specificity. Studies in cytokine or cytokine receptor knockout mice, or studies using cytokine antibodies, provide evidence for *in vivo* roles of these cytokines in certain inflammatory disease states. However, the effect of removing a cytokine either genetically or immunologically is dependent on the disease model and is not generalizable to all DMEs or transporters. This is most likely because of redundancy and/or cross-talk of cytokine pathways, as well as qualitative, quantitative, spacial, and temporal differences in cytokine secretion in different disease states.

As mentioned above, studies on cytokine regulation of DMEs and DTs to date have focused mainly on the ones known to be involved in hepatic APP regulation. However, there are receptors for many other cytokines and chemokines on hepatocytes and nonparenchymal cells in the liver (Table 19.3), and there is a need to discover which of these could be involved in DME and transporter regulation.

In certain diseases, DME and transporters could be regulated by factors other than cytokines. Activation of TLRs or other pattern-recognition receptors on hepatocytes could trigger changes in DME expression. Nonproteinaceous inflammatory mediators such as prostaglandins, or proteins or small molecules secreted by invading bacteria or parasites could also play a role. However, good evidence for or against such regulation is lacking at the present time.

19.4.2 Inflammation and Chronic Diseases

Research on the impact of inflammation on DMEs and DTs has tended to focus on acute inflammation and diseases or models of diseases that have inflammation as a

TABLE 19.3 Hepatic Target Cells of Cytokines and Chemokines

Cytokine/chemokine	Target Cells in Liver	References
IL-1	H SE KSC	29–32
IL-2	H K SC	33–35
IL-6	H SE KSC	36–38
IL-8	H	39
IL-12	Not described	—
IL-13	H SC	40,41
IL-17	H L	42,43
IL-21	Not described	—
$\text{TNF}\alpha$	K	44
$\text{IFN}\alpha/\beta$	H K SC	45,46
$\text{IFN}\gamma$	H SE K SC	31,47,48
MCP-1	H K SC	49–51
MIP-1 α	K	52
RANTES	K SC	52

In this table, a cell type is designated to be a target cell if receptors or a specific functional response have been detected. *Abbreviations:* L, liver-cell type unspecified; H, hepatocytes; SE, sinusoidal endothelial cells; KC, Kupffer cells; SC, stellate cells.

TABLE 19.4 Disease States with Inflammation as a Primary or Underlying Component

Primary	Underlying
Infection, septic shock	Cancer
Alcoholic and nonalcoholic fatty liver disease	Congestive heart failure
Rheumatoid arthritis	Hypertension
Gouty and osteoarthritis	Atherosclerosis
Tendinitis	Sickle cell disease
Fibromyalgia	Multiple sclerosis
Lupus (SLE)	Parkinson's disease
Asthma, chronic obstructive pulmonary disease (COPD)	Alzheimer's disease
Inflammatory bowel diseases	Chronic kidney disease/hemodialysis
Psoriasis	Obesity, metabolic syndrome, diabetes
Injury	

cause or primary component (Table 19.4). However, inflammation is now recognized as a condition associated with, or underlying, many chronic diseases and therefore has the potential to impact drug metabolism and disposition (Table 19.4). For example, inflammation is intimately involved in the development and progression of cancer, with inflammatory cytokines being produced both by immune cells and by the cancer cells themselves [53]. Cancer in humans is associated with reduced activity of CYP3A4, as detected by reduced clearance of its substrates erythromycin and docetaxel [53]. Clearance was negatively correlated with serum concentrations of APP and IL-6 levels [53,54], suggesting that the effect is dependent on the degree of inflammation associated with the disease. Examples of other diseases that have inflammation as an underlying component will be presented, but much more work is needed in this area.

19.4.3 Biomarkers

It will be apparent from the above discussion that cytokines themselves could be prognostic biomarkers for drug metabolism and disposition. This will be especially true for diseases in which a given cytokine is demonstrated to be mechanistically involved. Likewise, serum APP levels are used to measure inflammatory loads and are associated with disease outcomes such as in cancer [53]. C-reactive protein (CRP) is an APP that is readily detectable at low concentrations in human plasma, and which is measured in many routine health screening tests. As mentioned above, its plasma levels are negatively correlated with CYP3A4-catalyzed drug clearance in cancer patients, and it deserves further scrutiny as a predictive biomarker in cancer and other inflammatory diseases. If CRP levels are elevated, then one can infer that IL-6 and/or TNF α signaling pathways have been activated in hepatocytes suggesting that some DMEs and/or DTs will be affected. However, if other mechanisms of DME regulation predominate in a particular disease state, changes in drug metabolism or disposition may well occur before or without changes in APP secretion. This illustrates the need to understand the mediators and mechanisms of DME and DT regulation.

19.5 REGULATION OF THE CYP1 FAMILY

Sections 19.5–19.8 focus on hepatic expression of the major drug metabolizing P450 enzymes.

19.5.1 Bacterial Infection

Bacterial infections have been reported to downregulate protein and (or) CYP1A-associated activity in humans infected with *Helicobacter pylori* [55] or bacterial pneumonia [56]; pigs infected with *Actinobacillus pleuropneumoniae* [57]; and both mice and *Cyprinus carpio* (carp) infected with *Listeria monocytogenes* [58–60]. Following intracerebroventricular (i.c.v.) injection of *L. monocytogenes* in rats, CYP1A activity was significantly elevated at 48 h but returned to normal levels by 72 h [61]. In mice that developed hepatitis due to *Helicobacter hepaticus* infection, Cyp1a protein levels were induced [62], but the infection of mice with *C. rodentium*, a mouse intestinal pathogen, had no effect on Cyp1a2 mRNA levels measured seven days post infection [63,64].

19.5.2 Viral Infection

It has been known for several decades that humans infected with the influenza virus have depressed CYP1A activity as shown by their depressed theophylline clearance [2,65]. Hepatitis caused by infection with either the B or C virus also depressed CYP1A-associated activities and/or proteins in humans and mice [66–68]. Infection with HIV, on the other hand, had no significant effect on CYP1A2 activity as determined by urinary caffeine metabolite ratios [3].

19.5.3 Parasitic Infection

Both the hookworm (*Ancylostoma ceylanicum*) and liver fluke (*Fasciola hepatica*) downregulate hepatic mammalian CYP1A activity [69–71]. The caffeine and theophylline clearance of both children and adults infected with *Plasmodium falciparum* malaria is reduced [72,73]. The infection of rodents with *Plasmodium berghei* (ANKA strain), *P. falciparum*, or *Plasmodium chabaudi chabaudi* depresses their CYP1A activity levels [74–77]. Mice with schistosomiasis (infection of *Schistosoma mansoni*) have reduced hepatic 7-methoxy- and 7-ethoxyresorufin-*O*-deethylase (EROD), both Cyp1A-associated activities, during the early phases of infection and upregulation in chronic infection [78–80]. The hepatic microsomes of rats infected with *Taenia taeniformis* had lower EROD activity than those of rats that were uninfected [81].

19.5.4 Sterile Inflammation

Injection of LPS is a model of bacterial sepsis, and evokes an acute systemic inflammatory response. Owing to its ease of use and the large responses observed, it has been used in many laboratories to study how inflammation can regulate DME and DT expression. It is important to keep in mind that this model of end-stage disease is unlikely to predict how these systems will be affected in diseases where inflammation

is more localized and/or less fulminant. Most reports indicate that i.p. injection of LPS, derived from either *Escherichia coli* or *Salmonella abortus equi*, results in the down-regulation of CYP1A mRNA, protein levels, or activity in of rats or mice [64,82–84] as well as human beings [85,86]. However, LPS upregulates EROD activity in juvenile carp [87].

The administration of dextran sulfate sodium (DSS) is a well-characterized model of chemically induced inflammatory bowel disease (IBD) that has been used to study the regulation of hepatic P450 function in animals. In (DSS)-induced colitis as well as in collagen-induced arthritis or local inflammation induced by subcutaneous injection of casein or silver nitrate, downregulations of CYP1A-associated activities were observed [82,88,89]. The induction of cirrhosis by either carbon tetrachloride, thioacetamide or by bile duct ligation has been reported to cause the downregulation of CYP1A [90,91], which is likely to have inflammatory components. Conversely, Nakajima *et al.* [91] reported that D-galactosamine-induced hepatitis does not affect rat CYP1A protein levels. While both the Bacillus Calmette Guérin (tuberculosis, BCG) and influenza vaccines have been reported to downregulate theophylline clearance in humans [92,93], in another study the BCG vaccine given to rats did not affect phenacetin O-de-ethylation [94].

19.5.5 Cancer

Rodents with different sarcomas have been reported to have decreased CYP1A protein and (or) activity when compared to animals free of this condition [54,95]. In humans, the presence of hepatocellular carcinoma was reported to both to have no effect [68] and to downregulate phenacetin-deethylation [67], an activity which is associated with CYP1A.

19.6 REGULATION OF THE CYP2 FAMILY

19.6.1 CYP2A

Unlike most other CYPs, the CYP2A enzymes are often upregulated in inflammation or infection. This could be due to the fact that these enzymes are regulated by the redox-sensitive transcription factor Nrf2 [96,97].

Murine hepatitis caused by bacterial infection with *H. hepaticus* has been reported to elevate levels of Cyp2a5 [62], while infection with *C. rodentium* did not affect mRNA levels of the same enzyme [63,64]. In mice, hepatitis B virus infection has been shown to upregulate Cyp2a5 protein levels as well as activity [66,98,99]. In human beings on the other hand, when compared to uninfected controls, those infected by the hepatitis A virus had decreased coumarin-7-hydroxylation (a marker of CYP2A6 activity) [100], while infection with the hepatitis B and C viruses increased CYP2A6 protein levels [101].

The effect of parasite infestation on CYP2A-dependent coumarin 7-hydroxylation has been investigated in both rats and mice. Female C57BL/6 mice were not affected by infection with either *P. berghei* or *P. chabaudi chabaudi*, but age-matched animals with a DBA/2 background had elevated Cyp2a5 activity [76]. In rodents infected with *T. taeniformis* [81,102] and hamsters infected with the liver fluke, *Opisthorchis*

viverrini [103] the activity and (or) protein levels of CYP2As were elevated. Using mice suffering from schistosomiasis, Conte *et al.* [78] reported that there was no change in coumarin 7-hydroxylase activity but Manhaes-Rocha *et al.* [79] noted that while infestation did not change this activity in females, there was significant downregulation in male mice.

The administration of *E. coli* LPS downregulates Cyp2a5 mRNA levels but not the 7 α -hydroxylation of testosterone in several strains of mice [20,64,83,84,104,105]. Using a cDNA expression array, Fang *et al.* [106] reported the downregulation of CYP2A1 in rats given 0.5 mg/kg *S. abortus equi* LPS. Administration of lipotechoic acid, a component of gram-positive bacteria and a TLR2 agonist, transiently downregulated hepatic Cyp2a4 [107]. Colitis induced by 3% DSS in drinking water over seven days did not affect Cyp2a5 mRNA levels in the mouse [20].

19.6.2 CYP2B

Bacterial infections tend to downregulate CYP2B isoforms. The infection of either mice or rats with *L. monocytogenes* resulted in lower rates of CYP2B-dependent 7-pentoxoresorufin-O-dealkylation (PROD) and 7-benzoyloxyresorufin-O-dealkylation (BROD), respectively [59,61]. Pigs infected with *A. pleuropneumoniae*, mice infected with *C. rodentium*, and tuberculous guinea pigs all exhibited downregulated levels of CYP2B isoforms [20,57,64,108].

Humans infected with hepatitis B or C have been reported to have higher levels of hepatic CYP2B6 than uninfected controls, as assessed via immunohistochemical detection [101]. On the other hand, transgenic hepatitis V virus (HBV) mice had CYP2B protein levels and pentoxoresorufin O-dealkylase (PROD) activity comparable to ordinary mice [66,98]. Parasitic infection with liver flukes (*F. hepatica*) downregulated the N-demethylation of benzphetamine in hepatic microsomes of rats [70] and sheep [109]. In mice, infection with malaria downregulates BROD activity in a strain- and time-dependent pattern [75,110]. When using DBA/2 and Swiss Webster mice, Manhaes-Rocha *et al.* [79] reported that schistosomiasis generally did not affect Cyp2b-associated activity, while Conte *et al.* [78] reported a consistent downregulation of the same. In a different model of parasitic infection, microsomes from rats infected with tapeworms (*T. taeniformis*) had a lower activity of PROD than their uninfected counterparts [81].

The administration of *E. coli* LPS downregulates CYP2B in human beings [85,86], rodents [20,64,111], and in cell culture [112]. The TLR2 agonist lipotechoic acid greatly downregulates Cyp2b10 in mouse liver via a KC-dependent mechanism [107]. The downregulation of CYP2B isoforms has been reported for several chemically induced inflammatory conditions including collagen-induced arthritis [88] and thioacetamide-induced cirrhosis in the rat and DSS-induced colitis in the mouse [20] but not D-galactosamine-induced hepatitis of the rat [91]. Male Fisher 344 rats with a pituitary mammotropic tumor had decreased CYP2B activity, measured by hexobarbital sleeping time, as compared to cancer-free animals [113].

19.6.3 CYP2C

Bacterial infection of mice with *C. rodentium* or *L. monocytogenes* as well as the guinea pig with tuberculosis downregulated various CYP2C mRNAs or activities

[60,63,108]. Viral infections also tend to downregulate CYP2C-related activity. Mice infected with encephalomyocarditis virus and humans carrying the HIV or diagnosed with viral hepatitis all had downregulated CYP2C activity [98,114–117]. Callahan *et al.* [118] reported that after a single intravenous dose of the recombinant adenovirus serotype 5 vector, ranging from 5.7×10^6 to 5.7×10^{12} virus particles per kilogram, the activity and mRNA levels of CYP2C11 were upregulated. In a subsequent publication the authors reported that the adenovirus, administered without a transgene, suppressed CYP2C11 activity [119]. The authors concluded that the immunogenic and biological nature of a transgene cassette can influence changes in the 2C11 isoform and can be used to study part of the host response to viral infection, via its action on TLR3. Seminal work by Renton and Mannering [120] found that the double-stranded RNA poly I:C, an “interferon inducer” and TLR3 agonist, reduced hepatic content and activities of unspecified P450 enzymes. Its administration to rats was subsequently shown to downregulate CYP2C11 and 2C12 mRNAs and proteins [121,122].

The demethylation of aminopyrine, used as a marker of CYP2C activity is mainly metabolized by CYP2C11 in male rats [123]. Parasitic infections have been reported to downregulate aminopyrine-N-demethylation activity in several mammals including hamsters infected with *Leishmania donovani* [124] or *A. ceylanicum* (hook worm) [69], rats and sheep infected with *F. hepatica* (liver fluke) [125,126], and mice suffering from schistosomiasis [80].

Regardless of the route of administration, whether i.p or by i.c.v. injection, the administration of LPS from *E. coli* or *S. abortus equi* downregulates the levels of CYP2C mRNAs, protein expression and activity [20,64,82,83,106,127]. Mice administered an i.p injection (40 mg/kg) of bacillus Calmette-Guerin vaccine had normal levels of Cyp2c29 after 24 h [128], but the influenza vaccine has been reported to decrease aminopyrine clearance in humans [129]. In rodents, barium sulfate, carrageenan, celite, D-galactosamine, and kaolin have been used as models of sterile inflammation and have resulted in the reduction of CYP2C11 activity and (or) protein in rats [82,91, 130–132] and Cyp2c29 mRNA in mice [20].

Several reports have been made of the downregulation of CYP2C isoforms by cancer including unspecified metastatic cancers in humans [133], Murphy-Sturm lymphosarcoma, pituitary mammotropic tumor, and Walker 256 carcinosarcoma in rats [95,113]. Interestingly, the Engelbreth-Holm-Swarm sarcoma in mice upregulated Cyp2c39 and did not affect Cyp2c37 mRNA [134].

19.6.4 CYP2D

Bacterial infection with *C. rodentium* infection in female mice has been reported to downregulate Cyp2d22 and upregulate Cyp2d9 mRNA levels up to 10 days post infection [63,64]. Using male Wistar rats, Glazier *et al.* [77] reported that there was no significant difference in CYP2D1 activity between control animals and those infected with *P. berghei*, as measured by the α -hydroxylation of metoprolol.

Perhaps in one of the most dramatic demonstrations of the effects of infection on human DMEs, Jones *et al.* [3] reported that compared with healthy volunteers,

HIV-infected subjects had 90% lower CYP2D6 activity determined by the O-demethylation ratio of dextromethorphan metabolites.

LPS downregulated Cyp2d22 mRNA levels in C57BL/6 mice, while levels of Cyp2d9 were induced at 24 h in Refs 20 and 64. Compared to healthy individuals, humans with systemic lupus erythematosus had a decreased ability to convert debrisoquine to 4-hydroxydebrisoquine [135]. While treatment of rats with 2,4,6-trinitrobenzene sulfonic acid resulted in the downregulation of lidocaine metabolism [136], propranolol-7-hydroxylation was neither affected by DSS nor LPS treatments [82]. Treatment of mice with DSS did not affect Cyp2d9 but upregulated Cyp2d22 [20]. The expression of CYP2D was downregulated in rats with carrageenan-induced granuloma [137].

When proteomic profiling of mouse hepatic tissue was performed by multiplexed tandem mass spectrometry after isobaric tag for relative and absolute quantitation (iTRAQ) labeling it was reported that Engelbreth-Holm-Swarm sarcoma downregulated Cyp2d9 but did not affect the expression of either Cyp2d10 or 2d26 [134].

19.6.5 CYP2E

Bacterial infections in the pig (*A. pleuropneumoniae*) and mouse (*C. rodentium*) have been reported to depress CYP2E1 levels [57,63,64]. In mice, the hepatitis B virus upregulated Cyp2e1-associated 4-nitrophenol hydroxylation [66], and a retroviral infection resulted in increased Cyp2e1 activity at week 8 that returned to normal levels by week 16 [138]. In a malarial parasitic infection model, mice infected with *P. berghei* had increased Cyp2e1-associated activity [75], while in rats CYP2E1 activities were either upregulated or not affected [74,139]. Swiss Webster rats with schistosomiasis had decreased 4-nitrophenol hydroxylase activity at 90 days post infection [78], but only infected male rats showed significant elevation of *N*-nitrosodimethylamine *N*-demethylation at 30 days post infection [79]. While infection of female rats with *T. taeniformis* did not have a significant effect on 4-nitrophenol hydroxylase activity [81], hamsters infected with leishmaniasis or hook worms (*A. ceylanicum*) as well as sheep and rats infested with liver flukes (*F. hepatica*) all had depressed CYP2E1-associated activity compared to control animals [69,109,124,125].

The administration of LPS to rats and mice has been demonstrated to downregulate both expression and activity of CYP2E1 [20,64,82–84,104,106,111,127], although in one study CYP2E1 mRNA was induced [140]. Neither inflammation induced by kaolin nor D-galactosamine had significant effects on CYP2E1 protein levels of rats [91,132]. DSS-induced colitis suppressed 4-nitrophenol hydroxylase activity in rats but had no significant effect on mRNA levels in mice [20,82]. Administration of the tuberculosis vaccine to rats downregulated chlorzoxazone 6-hydroxylation [94], while in humans CYP2E1 activity is not altered by influenza vaccination [141]. In contrast, Muntane *et al.* [137] reported that rats with carrageenan-induced granuloma showed a strong depression of CYP2E1 RNA during the acute phase and recovered during the chronic phase. The presence of Engelbreth-Holm-Swarm sarcoma in mice and of metastatic cancers in human beings have both been reported to have no effect on CYP2E1 expression [133,134].

19.7 REGULATION OF THE CYP3 FAMILY

19.7.1 Infections

Bacterial infections have been reported to downregulate mouse Cyp3a11, 3a25, and 3a41 as well as rat CYP3A2 [61,63,64]. Critically ill patients with septic shock have been reported to be unable to metabolize midazolam [142]. Both humans and rodents infected with different forms of malaria exhibit downregulation of CYP3A activity [74,139,143]. While infection with hepatitis B or C virus upregulates CYP3A proteins [66,101], HIV-infected subjects had 18% lower hepatic CYP3A4 activity compared with age and sex-matched healthy volunteers [3]. Following a single intravenous dose of the recombinant adenovirus serotype 5 vector, the activity and mRNA levels of rat CYP3A2 were downregulated [118].

19.7.2 Sterile Inflammation

Treatment with LPS causes downregulation of CYP3A1 and 3A2 in rats, and Cyp3a11, 3a25, and 3a41 but not Cyp3a13 in mice [20,64,82–84,104,127,128,144,145]. The TLR2 agonist lipotechoic acid causes a moderate and transient downregulation of Cyp3a11 in mouse liver [107]. Administration of the TLR3 ligand poly rI:C to rats downregulates CYP3A2 [146]. Humans with rheumatoid arthritis had the same amount of urinary 6 β -hydroxycortisol as individuals who did not [147], but those with systemic lupus erythematosus, another inflammatory condition, had higher estrogen 16 α -hydroxylase activity [148]. Downregulation of rat hepatic CYP3A mRNAs, proteins, and activities has been observed in two different models of arthritis [6,7].

Both rats and mice treated with the tuberculosis vaccine had reduced CYP3A-associated activity [94,128], while humans immunized against the influenza virus had similar CYP3A activity measured by erythromycin breath test as those not immunized [149]. Treatment of rats with the irritants barium sulfate, celite, D-galactosamine, or kaolin did not affect CYP3A2 protein levels [91,132], while induction of a local inflammatory response with turpentine in the rabbit resulted in the downregulation of CYP3A6 protein [150]. In rats, carrageenan-induced granuloma downregulated CYP3A1 mRNA and catalytic activity [137].

19.7.3 Cancer

There is good evidence that CYP3A-mediated clearance is inhibited in people with advanced cancer. Erythromycin clearance was reduced, and negatively correlated with plasma IL-6 and acute-phase protein markers, in individuals with various different associated cancers [53]. Another study found similar results with cancer patients having decreased midazolam clearance and increased exposure to docetaxel [151]. An earlier study on metastatic cancers found no effect on CYP3A protein levels in surgical liver samples [133]. In mice transgenic for a CYP3A4 promoter- β -galactosidase reporter gene, implantation of a murine sarcoma caused downregulation of the transgene as well as the native Cyp3a11 mRNA [54]. These were associated with elevated serum levels of IL-6.

19.8 REGULATION OF THE CYP4 FAMILY

19.8.1 CYP4A

Compared to uninfected animals, mice infected with *C. rodentium* had significantly lower hepatic levels of Cyp4a10 and 4a14 mRNA, and CYP4As were the most profoundly affected of all P450s [63,64]. Infection of mice with the parasite *S. mansoni* resulted in depressed Cyp4a protein levels in the liver [80].

In rats, we found that *E. coli* LPS treatment upregulated CYP4A2 and 4A3 mRNA levels [127]. While there was no difference between the ability of control and treated male Sprague-Dawley rats to carry out ω -lauric acid hydroxylation, the same treatment resulted in upregulation of the activity in male Fisher 344 rats. However, another study reported that treatment of male Wistar rats with *S. abortus equi* LPS caused downregulation of CYP4A1 and 4A3 [106]. In mice, hepatic lauric acid ω -hydroxylation and Cyp4a10 mRNA levels are depressed by treatment with *E. coli* endotoxin [20,64,83,152]. Modulation of Cyp4a14 appears to be strain-dependent in mice with LPS downregulating levels in C57BL/6J [64] but not in C3H strains [20].

Treatment of rats with the sterile irritants barium sulfate or celite upregulated CYP4A1 mRNA but did not affect either CYP4A2 or CYP4A3 [132]. Microsomes from rats with collagen-induced arthritis had higher lauric acid hydroxylation when compared to nonarthritis rats [88]. In contrast, DSS-induced colitis in mice downregulated Cyp4a10 and 4a14 mRNAs [20]. Muntane *et al.* [137] reported that the presence of carrageenan-induced granuloma in rat depressed CYP4A levels.

19.8.2 CYP4F

Unlike with CYP4As, relatively little is available on the modulation of CYP4Fs by either inflammation or infection. In mice infected with *C. rodentium*, Cyp4f15 mRNA was downregulated while Cyp4f18 was upregulated [63,64]. Treatment of rats with *E. coli* LPS suppressed CYP4F4 and 4F5 expression by 50% and 40%, respectively [153,154], whereas CYP4F5 mRNA was upregulated [153]. LPS from *S. abortus equi* also downregulated CYP4F4 in rat liver after 4 h [106]. In hepatocytes, LPS downregulated CYP2C11, 4F4, and 4F5 [154].

19.9 FLAVIN MONOOXYGENASES

Flavin-containing monooxygenases (FMOs, EC 1.14.13.8) oxygenate substrates with a soft nucleophile, usually nitrogen or sulfur. While in many respects FMOs are similar to P450s and have overlapping substrate specificities, they often yield distinct metabolites. In rats, LPS treatment evoked decreases in hepatic content of FMO1 mRNA and protein, as well as of FMO activities, and these effects were attenuated by inhibition of nitric oxide synthases, suggesting a role for NO in the effect [155]. LPS treatment of mice depressed hepatic FMO1, 3, and 5 mRNAs but did not affect FMO4 mRNA [1]. Mice infected with *C. rodentium* had downregulated levels of FMO1, 3, 4, and 5 [1], and the downregulation of FMO3 persisted for at least nine days after the infection was resolved. The oxidation of nicotine to nicotine-1'-N-oxide is catalyzed by FMOs [91], and this activity was not changed in rats with D-galactosamine-induced hepatitis, in

comparison with the controls, but was significantly decreased in thioacetamide-induced cirrhotic rats [91].

19.10 CONJUGATION ENZYMES

19.10.1 Uridine 5'-Diphospho-Glucuronosyltransferases

The UDP-glucuronosyl transferases (UGTs) are a superfamily of glycosyltransferases (EC 2.4.1.17) that catalyzes the glucuronidation reaction. Mammalian UGTs are divided into four families, UGT1, UGT2, UGT3, and UGT8.

In animals with bacterial or parasitic infections, UGTs were reported to be either downregulated or not affected. Carp infected with *L. monocytogenes*, mice infected with *Plasmodium berghei*, *P. chabaudi chabaudi*, or *S. mansoni* and pigs infected with *A. pleuropneumoniae* had UGT activity similar to uninfected animals [58,74,76,79]. On the contrary, *P. berghei* infected rats were reported to have depressed UGT activity [77,156,157]. Infection of mice with *C. rodentium* resulted in the downregulation of Ugt1a1, 1a9, and 2b5 mRNA but not Ugt1a2 or 1a6 in the liver [158].

The i.p. administration of LPS to rodents did not affect transcription of UGT1A2 and 1A6, but it downregulated Ugt1a1 and 1Aa9 in mice [158] and UGT1A1, 1A6, 2B1, and 2B6 in rats [159]. Turpentine administered intramuscularly to rats was reported to have no effect on 4-nitrophenol glucuronidation but downregulated hepatic UGT isoforms from the UGT1 and two families [160]. Analysis of mRNA extracted from liver tissue samples of patients with fibrosis revealed general downregulation for several UGT1A and UGT2B isoforms that reached statistical significance only for UGT1A4, 2B4, and 2B7 [161]. In the rat, carbon tetrachloride-induced cirrhosis upregulated UGT2B1 [162] but did not affect 4-nitrophenol conjugation by a perfused rat liver [163].

In rodents with induced cancer, the reported modulation of UGTs is varied. Rats with 2-acetylaminofluorane-induced liver preneoplastic nodules had upregulated mRNA [164], while mice injected with Engelbreth-Holm-Swarm sarcoma cells had normal levels of Ugt1a7 but reduced levels of Ugt2b5 [134].

19.10.2 Sulfotransferases (SULTs)

The sulfotransferases (SULTs) (EC 2.8.2) are a gene family of enzymes that catalyze the transfer of a sulfonate group (SO_3^-) from a donor molecule, 3'-phosphoadenosine 5'-phosphosulfate, to a variety of acceptor molecules in a process referred to as *sulfonation* or *sulfurylation*.

In the rat, parasitic infections have been reported both to upregulate [156] as well as downregulate [125,157] SULT activity, while the LP-BM5 retrovirus that causes murine leukemia did not cause significant differences in the recovered urinary acetaminophen sulfate between infected and uninfected mice [165]. Intraperitoneal injection, or the treatment of rodent perfused liver with LPS, has been reported to cause the downregulation of several isoforms in the SULT1 and SULT2 families. In comparison to healthy individuals, SULT1A1 activity increased almost 10-fold in patients with hepatocellular carcinoma secondary to chronic hepatitis B virus infection [68]. Transgenic mice injected with Engelbreth-Holm-Swarm sarcoma cells had higher levels of SULT1A1 but depressed SULT2A1 protein levels [134].

19.10.3 Glutathione S-Transferases (GSTs)

The glutathione S-transferases (GSTs) (EC 2.5.1.18) are a superfamily of enzymes that catalyze the nucleophilic attack of the sulfur atom of glutathione on an electrophilic group on a variety of lipophilic compounds. On the basis of amino acid sequence similarities, six classes of cytosolic GSTs are recognized in mammalian organisms, namely, alpha, mu, omega, pi, sigma, theta, and zeta designated A, M, O, P, S, T, and Z, while mitochondrial GSTs are designated kappa (K).

In humans, patients suffering from *Plasmodium vivax* malaria had about half the overall GST activity of patients without malaria [166]. De-Oliveira *et al.* [76] reported that when mice were infected with either *Plasmodium chabaudi chabaudi* or *P. berghei*, the conjugation of glutathione to 1-chloro-2,4-dinitrobenzene (CDNB) in mouse liver did not change. All cytosolic GSTs, except class Theta are able to carry out this reaction. Infection with *Plasmodium yoelii nigeriensis*, on the other hand, reduced CDNB conjugation [167], while infection with *Angiostrongylus cantonensis* upregulated this activity [168].

Infection with hepatitis C virus (HCV) has been reported to upregulate levels of GSTA to over 150% when compared to HCV negative healthy subjects [169,170]. Viral infection of mice (hepatitis B or C) generally causes the upregulation of GST activity [66,169–171]. While the treatment of both F111 rat fibroblasts and human hepatoblastoma (HepG2) cells with SV40T antigen did not affect the GST levels as measured by Northern blotting, infection of HepG2 cells with the hepatitis B virus resulted in downregulation of GSTA [171].

The i.p. administration of up to 2 mg/kg *E. coli* endotoxin (LPS) has been reported to elicit no significant changes in mouse [145], juvenile carp (*C. carpio*) [87], or rat [111] GSTs. Choi and Kim [172] reported that i.v. LPS treatment downregulated GSTA and GSTM classes in rat liver. Endotoxin from *Salmonella typhimurium* and *S. abortus equi* have also been documented to reduce the expression or protein levels of GSTs in the A, M, and K classes [105,106,173] in rat liver.

19.10.4 Arylamine N-Acetyltransferases (NATs)

N-acetyltransferases (NATs) (EC 2.3.1.5) are enzymes that catalyze the transfer of an acetyl group from acetyl-CoA to an aromatic or heterocyclic amine, hydrazine, hydrazide, or N-hydroxylamine acceptor substrate. Humans have two isoforms, NAT1 and NAT2, while rodents have a third, Nat3 [174]. Compared with age and sex-matched healthy volunteers, HIV-infected subjects had 53% lower NAT2 activity [3].

19.11 EXTRAHEPATIC METABOLISM

19.11.1 Intestine

The intestinal P450 profile differs from that of the liver and shows large interindividual variation in the expression levels of individual P450s. CYP3A and CYP2C9 are the major intestinal P450s in humans, on average accounting for 80% and 15%, respectively [175]. The small intestine is the first site to metabolize orally ingested xenobiotics. Intestine-specific ablation of cytochrome P450 reductase in mice demonstrated that P450-catalyzed nifedipine metabolism in the small intestine plays an important role in the first-pass clearance of the nifedipine, and possibly other drugs [176].

CYP3A, P-glycoprotein (PGP) (mdr1), and MRP2 are important barriers to the absorption of many clinically important drugs in the intestine [177]. In the duodenum of pediatric patients with Crohn's disease, CYP3A mRNAs were higher compared with control groups [178]. Consistent with these observations, in a trinitrobenzenesulfonic acid model of colitis, rat colonic tissue samples showed increased activities of PGP-related efflux and CYP3A-catalyzed metabolism *ex vivo*. However, no change was observed in CYP3A metabolic activity and expression in the respective microsomal fractions [179]. The author suggested that increased metabolism could be due to infiltrating cells at the inflammation site [179]. Greer *et al.* studied the levels of nuclear receptors (NRs) and DME mRNAs in duodenum and colon biopsies of dogs with naturally occurring IBD or food responsive diarrhea (FRD) compared with healthy animals. In the duodenum, peroxisome proliferator-activated receptor- γ (PPAR γ), constitutive androstane receptor (CAR), pregnane X receptor (PXR), and retinoid X receptor- α (RXR α) mRNAs were not different in any of the groups, while PPAR α was elevated in colon only. Duodenal MRP2, CYP3A12, and SULT1A1 mRNAs were elevated in both FRD and IBD, whereas MDR1 mRNA was only elevated in FRD [180].

MDR1, MRP2, and CYP3A mRNAs were decreased by 50%, and CYP3A-mediated metabolism of 7- amiodarone and 7-benzyloxyquinoline were also decreased by $\sim$ 50% in the jejunum of LPS-treated rats [177,181]. The activity of PGP and CYP3A was also downregulated [181].

19.11.2 Lung

In human lung, CYP1A1 (in smokers), CYP1B1, CYP2B6, CYP2E1, CYP2J2, and CYP3A5 proteins are all expressed, as well as FMO and phase II conjugating enzymes [182]. Somers *et al.* [183] compared the expression and metabolizing activities of phases I and II enzymes in freshly isolated human lung parenchymal cells and cryopreserved human hepatocytes, showing that P450 gene expression and activities were generally lower in lung than in liver, whereas expression of all sulfotransferase isoforms in lung was similar to or higher than that in liver.

Rat pulmonary CYP1A and CYP2B1 activities were reduced by 3- and 1.5-fold, respectively 24 h after administration of LPS, while LPS had no effect on basal GST activity in both lung and kidney [184]. Levels of Cyp4a12 mRNA, the only detectable Cyp4a in mouse lung, were enhanced by fourfold in animals injected with IL-1 β [185]. During the acute inflammatory phase of ovalbumin-induced allergic airway disease the pulmonary mRNA levels of Cyp2e1, Cyp2f2, Cyp2j6, Cyp4b1, and Cyp8a1 were decreased while the mRNA levels of Cyp4f18, Cyp5a1, and Cyp7b1 were elevated [186].

19.11.3 Kidney

The highest concentrations of P450 enzymes in the kidney are found in the S₃ segment of the proximal tubules in the renal cortex [187]. LPS treatment caused the induction of renal CYP4A mRNAs in both rats [132,188] and SV/129 mice [152]. In contrast, LPS injection decreased renal CYP 4A1 and CYP 4A activity 4 h after injection in rat [189].

Anwar-Mohamed *et al.* reported that LPS injection was associated with the down-regulation of CYP1A1, 1B1, 2C11, and 2J3 mRNAs in rat kidneys and hearts [188].

These authors also reported that CYP4F1, 4F4, and 4F5 were downregulated in the kidney, whereas Kalsotra *et al.* previously found no change of CYP4F1, 4F5, and 4F6 after LPS treatment [153]. The downregulation of the CYPs involved in arachidonic acid epoxidation (2C11 and 2J2) was accompanied by a concomitant decrease in epoxyeicosatrienoic acids produced by these enzymes [188].

CYP2E1-mediated chlorzoxazone-6-hydroxylase activity and CYP2E1 mRNA and protein levels, as well as mRNAs of CYP4A2 and 4A3 were increased in rat kidneys 48 h after treatment with the particulate irritants SiO₂, BaSO₄, and kaolin [132]. BaSO₄ also induced renal CYP4F1 and 4F6 expression [153].

Infection with *C. rodentium* did not affect renal expression of most P450 isoforms (Cyp1a2, 2a5, 2c29, 2e1, 3a11, and 3a13) in C3H/HeOuJ mice. However, renal Cyp4a10 and 4a14 mRNAs were significantly downregulated [190]. Renal UGT isoforms were also relatively unaffected, except for Ugt2b5 which was induced [158]. The oxidation of *trans*-diethylstilbestrol to diethylstilbestrol-4',4'-quinone by P450 in microsomes of estrogen-induced kidney tumors of male hamsters was only 10–20% of the rate compared to control kidney microsomes [191]. Significantly, total P450 content of the tissue surrounding the tumors was also reduced compared to control tissue. In contrast, traumatic brain injury in rats resulted in an elevation of renal CYP1A and CYP4F levels measured 24 h and two weeks after injury [153].

19.11.4 Central Nervous System

CYP1A1, CYP1A2, CYP2B1, CYP2B2, and CYP2E1 proteins are detected in the rat and/or human brain [192], and CYP2C29, CYP2D4, CYP2E1, CYP4F, and CYP3A9/11/13 are known to be expressed in brain [193]. Recently, higher levels of expression of CYP3A43 were discovered in brain as compared to liver across different ethnic populations [194].

The i.c.v. injection of LPS has been employed as a model of CNS inflammation, as it produces a robust inflammatory response in the brain characterized by the activation of microglia and astrocytes and the induction of inflammatory cytokine (TNF α , IL-6, and IL-1 β) production [18,195,196]. This causes downregulation of CYP1A proteins and associated ethoxyresorufin *O*-dealkylase (EROD) activity in the brain [196]; reduced EROD activity in the brain was also observed after systemic LPS injection [195].

In rats with inflicted traumatic brain injury, hippocampal expression of CYP4F4 and 4F5 is transiently elevated before being downregulated, and hippocampal CYP4F proteins are reduced to 20% of control within 24 h [154]. At this time point, CYP4F1, CYP4F4, CYP4F5, and CYP4F6 are all substantially downregulated in the frontal and occipital lobes of the brain as well [197].

19.12 DRUG TRANSPORTERS

DTs play important roles in drug metabolism and disposition, and they can be classified into efflux and uptake transporters. The largest family of efflux transporters is the ATP-binding-cassette (ABC) family, which are involved in the cellular efflux of many clinically important drugs. The family of uptake solute carriers (SLCs) also plays a central role in the cellular trafficking of numerous drugs [198].

Among the ABC drug efflux transporters, PGP/ABCB1, which is encoded by the multidrug resistance gene *MDR1* in humans and *MDR1a* and *MDR1b* in rodents, multidrug resistance-associated proteins (MRP1–3/ABCC1–3), and breast cancer resistance protein (BCRP/ABCG2) have particularly important roles in clinical drug disposition [198]. These transporters are highly expressed in epithelia of the intestine, liver, kidney, placenta, and blood–brain barrier, and they display a great deal of substrate overlap [198]. In addition, PGP, BCRP, and MDRs are known for their involvement in the extrusion of anticancer drugs from tumor cells and development of multidrug resistance. Members of the organic anion-transporting peptide (OATP, SLC21) family, especially OATP1 and OATP2, are important in the cellular uptake and oral bioavailability of a wide array of anionic drug substrates.

Inflammation also causes alterations in the expression and activity of DTs, contributing to changes in the absorption, distribution, and clearance of drugs and resulting in, for example, altered toxicity and compromised secretion of drugs into bile or urine [134,198]. Effects of inflammation on DT are described in a recent review by Teng and Piquette-Miller [199], and are summarized here in Table 19.5.

TABLE 19.5 Effect of LPS and Turpentine-Induced Inflammation on Various Drug Transporters

Transporter	Species	Tissue	LPS	Turpentine
MDR1a	Mouse	Liver	↓	↓
	Rat	Liver	↓	↓

19.12.1 LPS Model

As described above, LPS injection is a classic model of the inflammatory response, triggering the release of the proinflammatory cytokines IL-6, IL-1 β , and TNF α and eliciting numerous changes in hepatic DMEs and DTs. In rats, hepatic mRNAs of MRP2, MRP6, OATP1, OATP2, OATP4, sodium taurocholate cotransporting polypeptide (NTCP), bile salt export pump (BSEP), organic cation transporter (OCT)1, and OAT3 were dramatically and rapidly downregulated following injection of LPS. In contrast, the efflux transporter mRNAs MRP1, MRP3, and MDR1b were induced; and MRP5 and OAT2 were unaffected [200]. LPS injection in mice results in mRNA downregulation of many hepatic DTs including Mdr1a, Mdr1b, Mdr2, Mrp2, Mrp6, Oatp1, Oatp2, Oatp4, Bsep, and Ntcp [198,201]; whereas, Mrp1 and Mrp5 are induced [201]. Note that Mdr1b mRNA levels are decreased in mice and increased in rats. Nevertheless, in both species decreased hepatic PGP protein expression is seen [202–204]. The effects of LPS on transporter expression were similar in wild-type (WT) C57BL6/J mice and in mice null for TNF α -receptor 1, IL-1 receptor, IL-6 or inhibitor of κ B kinase β (IKK β) [201].

19.12.2 Sterile Inflammation

Injection of the TLR2 agonist lipotechoic acid caused a transient downregulation of Mrp2 mRNA in mouse liver, whereas Mdr1b was induced and Mrp3 was unaffected [107]. Initial studies detected decreases of 50–70% in the hepatic expression and activity of PGP within 24–48 h after administration of turpentine [205]. These reductions, which occurred at the level of mRNA, were shown to stem from suppression of MDR1a and MDR1b nuclear gene transcription in turpentine-treated rats [206]. The effects of turpentine on hepatic transporter expression in mice are well summarized by Teng and Piquette-Miller: Mdr1a, Mdr1b, Mrp2, Mrp3, Oatp2, Bsep, and Ntcp are all downregulated [207].

19.12.3 Viral Infection

Nakai and coworkers studied the hepatic expression of CYP enzymes and DTs in chronic hepatitis C patients. They found that relative mRNA levels of CYP3A4 and OATP-C all were substantially downregulated compared to non-HCV livers. This correlated with the stage of fibrosis but not with inflammation [208]. CYP 1A2, 2E1, NTCP, and OCT1 were apparently elevated in the F1 stage of fibrosis, and then declined back toward normal levels as fibrosis progressed [208].

Treatment of rats with the TLR3 ligand poly I:C resulted in elevated plasma concentrations of IFN γ , TNF α , and IL-6, and significant downregulation of hepatic MRP2, BCRP, SLCO1A4, and SLC10A1 mRNAs; whereas MDR1b and MRP3 mRNA levels were significantly induced. Hepatic PGP, MRP2, and BCRP were significantly downregulated at the protein level. Many placental transporter mRNAs were also downregulated [146].

19.12.4 Other Inflammatory Diseases

Cholestasis in mice caused by bile duct ligation caused a downregulation of hepatic Oatp1 and induction of Mrps 1, 3, and 5. In the same model Oatps 2, 4, 5, 9, 11,

12, and 14; Mrps 1, 2, 4, 6, 7, and 9; and Ntcp and Bsep were unaffected [201]. The changes in DT expression were similar in mice lacking the genes for TNF α -receptor 1, IL-1 receptor, IL-6, or IKK β , suggesting that compensatory or redundant mechanisms exist for this regulation [201]. In another model, mice inoculated with rotavirus (which causes intrahepatic cholestasis) had a downregulation of canalicular and basolateral hepatobiliary DTs and their regulatory NRs and a concomitant increase in inflammatory cytokines [209].

Several hepatic DTs, as well as CYP enzymes, are altered in animal models of end-stage renal disease (ESRD) [210–212]. For example, PGP is induced in the liver while OATP2 is downregulated. However, the possible contribution of inflammation to these effects is unknown, and uremic mediators may be responsible [211]. Diabetes is another disease with a strong inflammatory component. Streptozotocin-induced diabetic rats display decreased levels of MDR1a, MRP2, and BCRP and increased levels of MDR3 [213].

19.12.5 Regulation in Extrahepatic Tissues

Inflammation affects DT expression in the intestine, and can potentially affect drug absorption and oral bioavailability [198]. The mRNA and protein expression of PGP/MDR1a, MRP2, and CYP3A are downregulated by approximately 50% in the jejunum of LPS-treated rats [177]. The functional effects of these changes on absorption of PGP and MRP2 substrates were demonstrated in intestinal sections isolated from control and LPS-treated rats [177]. In the DSS model of colitis, mice have reduced expression of Mdr1a mRNA and PGP and PXR proteins in their large intestines [214]. In patients with active ulcerative colitis, mRNA and protein levels of BCRP and PGP were significantly reduced in the colons and rectums of individuals with active ulcerative colitis compared with controls or patients in remission, and were negatively correlated with the levels of IL-6 mRNA [215]. MRP2 mRNA, protein, or activity are decreased in the intestine of LPS-treated rats and in several other models of inflammation, including cholestasis and chronic renal failure [198].

PGP is expressed abundantly in several cell types within the CNS [198]. LPS-induced downregulation of PGP/MDR1a in brain tissues has been found to increase intracranial drug accumulation in rodents. Downregulation of PGP protein following i.v. LPS treatment was associated with increased accumulation of doxorubicin in mouse brains [216]. The i.c.v. LPS also downregulated CNS levels of PGP, Oatp2, and Mdr1a mRNAs, accompanied by elevated brain levels of the PGP substrate digoxin [204], demonstrating that localized CNS inflammation produces a loss of PGP function in the blood–brain barrier. The reduction of brain Mdr1a expression was blocked in mice with mutated TLR4, confirming that the activation of TLR4 receptor signaling is the major pathway involved in the reduction of brain Mdr1a expression [134].

Likewise, systemic and CNS inflammation produced by i.p. or intracranial administration of LPS triggered significant decreases in the expression of MDR1a mRNA in rat brain with analogous increases in the brain accumulation of PGP substrates such as ^{99m}Tc -sestamibi and digoxin [198]. Similar to liver, inflammation also resulted in a pronounced decrease of OATP2 in brain [204]. While hepatic mRNA levels of all Mdr isoforms are reduced in LPS-treated mice, Hartmann *et al.* reported that Mdr1b levels

are increased in kidney [217]. However, another study showed decreased renal expression of Mdr1a and Mdr1b mRNA [218]. Further studies are needed to understand the renal regulation of DTs respect to inflammation.

19.13 ROLES OF CYTOKINES

19.13.1 IL-1, TNF α , IL-6, and IFNs

Most investigations of the roles of cytokines in the regulation of DMEs and DTs have focused on IL-1, TNF α , and IL-6, as they are the major proinflammatory cytokines regulating hepatic acute-phase genes. IFNs have been studied because viral infections trigger the production of IFNs, and because IFN inducers can mimic the effects of viral infection on the P450 system [219]. Cytokines administered *in vivo* or incubated with cultured hepatocytes have enzyme-selective effects on CYP expression, and cultured hepatocytes have served as good models for the *in vivo* effects of cytokines [8,219–221].

IL-1, TNF α , and IL-6 as well as IFNs are capable of downregulating basal and drug-induced expression of many different CYP enzymes in cultured human and animal hepatocytes. For example, 72 h of IL-6, IL-1 β , or TNF α treatment resulted in downregulation of mRNA levels and enzyme activities of CYP1A2, CYP2C, CYP2E1, and CYP3A in human hepatocytes [222]. More recently, we showed that, whereas CYP3A4 and CYP2C8 mRNAs were downregulated by IL-6, TNF α , IFN γ , or IL-1 β in primary human hepatocytes within 24 h of treatment, other CYP2Cs and CYP2B6 showed cytokine-specific effects [8]. Of these cytokines, IL-6 downregulated the mRNAs of all CYPs tested except CYP2C18. Exposure of primary human hepatocytes to IFN γ resulted in downregulation of mRNA levels of influx transporters NTCP, OATP2B1, OATP1B1, and OATP1B3, as well as the efflux transporters MDR1, MRP2 protein, MRP3, BCRP, and BSEP [223].

In terms of inducible expression, IL-6, IL-1 α , or TNF α treatment caused suppression of β -naphthoflavone-induced CYP1A1/2 mRNAs (with TNF α as the most potent) and of rifampicin-induced CYP3A4 mRNA (with IL-6 as the most potent) [224].

IL-1 β , IL-6, TNF α , or IFN α all downregulated CYP2C11 mRNA in cultured rat hepatocytes. IL-6 was the most potent but least efficacious of these, and IFN γ had no effect [225]. However, IFN γ treatment did suppress both basal and induced CYP3A expression in rat hepatocytes [226]. Rat hepatocyte CYP4F5 is induced by IL-6, IL-1 β , or TNF α treatment [227]. IL-10, an anti-inflammatory cytokine, suppressed CYP4F1, 4F4, and 4F5 expression [227].

IL-6, IL-1 β , and TNF α suppress both P450- and UGT-dependent enzyme activities in primary pig hepatocytes, with IL-6 effects being slower than those of the other two cytokines [228]. IL-6 and TNF α produce stronger repression of CYP 1A1, 2C8, and 3A4 in porcine hepatocytes than in human hepatocytes [229].

IL- β , TNF α , or IL-6 can also downregulate DTs in hepatocytes [230]. In primary human hepatocytes TNF α or IL-6 each caused the mRNA downregulation of influx transporters NTCP, OATP1B1, OATP1B3, OATP2B1, OCT1, and OAT2, and induced MRP3; whereas, IL-6 but not TNF α suppressed MDR1, MRP2, and BCRP [231]. On the other hand, IFN γ treatment downregulated mRNAs for NTCP, OATP 2B1, OATP1B1, and OATP1B3 as well as the drug efflux pumps MRP1, MRP2, MRP3, BCRP, and BSEP [223].

Many of the effects of cytokines on hepatocytes described above have also been observed when the same cytokines are administered *in vivo*, and this has been reviewed extensively [219]. For example, IFN γ administration to male rats suppressed CYP3A2 mRNA expression and activity [232]. IL-1 and/or TNF α administration resulted in the suppression of total P450 content, activities and/or P450 gene expression in rat and mouse liver [219]. Injection of IL-1 β *in vivo* resulted in the suppression of rat female-specific CYP2C12 mRNA and protein [233], and also caused a decreased expression of CYP2C11 and CYP3A2, but not CYP2E1 in male rats [234]. TNF α administration causes the suppression of rat CYP3A2 and CYP2C11 mRNAs and proteins [235].

Administration of IL-6, IL-1 β , or TNF α to mice has been shown to alter the expression of several DTs, especially via downregulation. These effects are summarized in Table 19.6, where a comparison of the impacts of cytokines on DTs in mice *in vivo* with those in cultured human hepatocytes reveals much commonality between the two model systems [199,230]. IL-1 β , IL-6, and TNF α also caused differential effects on DT expression in human and murine hepatoma cell lines [199].

TABLE 19.6 Comparison of Cytokine Effects on Hepatic Transporter Expression in Mouse

Transporter	Liver and Human Hepatocytes		
	Cytokine	Mouse liver	Primary Human Hepatocytes
Mdr1a	IL-1 β	↓	↓
	IL-6	↔	↓
	TNF α	↔	↔

Most of the *in vivo* effects of cytokines on human drug metabolism have been observed with type I IFNs α or β , and these studies are well summarized in a recent review by Mahmood and Green [5]. The effects observed were highly variable and often contradictory. The response of DMEs to IFNs is obviously influenced by genetic, environmental, or other factors.

19.13.2 Other Cytokines

Data for cytokines other than the ones mentioned above is scant, and there is a need for more research in this area. The most information exists for IL-2, which is produced by T cells upon T-cell receptor activation, and functions in T-cell development and killer T-cell activation. Injection of IL-2 in rats modestly induced CYP2D mRNA and protein, as well as bufuralol demethylase activity. Several other microsomal drug metabolizing activities were also induced, whereas others were unaffected [236]. On the other hand, IL-2 treatment of cultured rat hepatocytes for 24 h was associated with downregulation of CYP3A2 and 2C11 mRNAs as well as proteins of the 1A, 2B, 2C, 2D, and 3A subfamilies [33], and these effects were attributed to increased expression of the transcription factor c-myc [237]. IL-2 receptor was identified on hepatocytes by immunofluorescence labeling. IL-2 also downregulated rifampicin induced, but not constitutive, CYP3A6 expression in cultured rabbit hepatocytes [238]. Patients with secondary hepatic cancer receiving treatment with IL-2 had reductions in the hepatic protein levels and activities of CYP1A2, CYP2C, CYP2E1, and CYP3A4 enzymes that were dependent on the IL-2 dose [239]. Cell culture studies revealed that IL-2 was able to downregulate CYP3A4 only when hepatocytes were cocultured with KCs [240]. Basiliximab and daclizumab are inhibitory anti-IL-2 receptor (α -chain) monoclonal antibodies approved by the FDA in 1998 to reduce organ transplant rejections. Daclizumab also tested successfully in a phase II trial for MS. Pediatric patients given basiliximab experienced high cyclosporine blood levels and toxicity [241]. This suggests that the antibody is countering an induction of CYP3A4 by IL-2, which is puzzling in view of the clinical observation of downregulation by IL-2 treatment [239].

IL-4 has important roles in T-cell development as well as in humoral and adaptive immunity. Its well-characterized targets are T cells and B cells. CYP2E1 mRNA was rapidly induced by IL-4 in human B16A2 hepatoma cells, which involved two independent signaling pathways: IRS1/2 via NFATc1 and a Stat6-dependent pathway [242]. In human hepatocytes, three days of IL-4 treatment induced the expression of CYP2E1 as well as GSTA1/2 mRNAs. [243], but the length of treatment may suggest an indirect effect.

IL-8 is a chemokine (chemotactic for neutrophils) and also has angiogenic activity. We found that IL-8 had no effect on the expression of CYP2C11 in rat hepatocytes, at concentrations up to 10 ng/mL [244]. However, IL-8 induces expression of the retinoic acid-catabolizing enzyme CYP26A1 in leukemia cells [245]. Since CYP26A1 contributes significantly to the hepatic clearance of the chemotherapeutic agent all-trans retinoic acid, its regulation in liver by IL-8 might be important to study [246].

IL-10 is a monocyte-derived cytokine that is considered to be anti-inflammatory, as it antagonizes many inflammatory pathways. However, when healthy humans were given 8 mg/kg IL-10 for six days, it evoked an APR characterized by reduced albumin and elevated ferritin in the serum [247]. CYP3A4-mediated midazolam clearance was

modestly inhibited by 12%, but there was no effect on CYP1A2-, 2D6-, or 2C9-catalyzed drug clearance [247]. Another study found no effect of IL-10 treatment on the pharmacokinetics of prednisolone, a CYP3A4 substrate [248,249]. We found that IL-10 suppressed CYP4F1, 4F4, and 4F5 expression in rat hepatocytes [227].

IL-11 is a member of the IL-6 family of cytokines whose receptors dimerize with the gp130 protein to initiate cellular signaling. It is an inducer of APPs, and we showed that it also downregulates CYP2C11 mRNA in rat hepatocytes with an EC₅₀ of ~100 pg/mL [244].

IL-17 is actually a family of highly related cytokines that are considered to be proinflammatory due to their ability to stimulate cytokine production from many cell types. It induces the expression of the cholesterol-catabolizing enzyme CYP7B1 in synovio-cytes, where it may be involved in maintenance of inflammation in rheumatoid arthritis [250]. The effects of IL-17 on liver or on drug metabolizing P450s are not known.

19.13.3 Knockout Mice

The aforementioned abilities of cytokines to downregulate P450s or DTs in hepatocyte model systems and in animals *in vivo* does not address their physiological importance. To address the question of what cytokines are important for the *in vivo* regulation of P450 isoforms and DTs caused by a given stimulus, cytokine null mice or cytokine receptor null mice have been used.

IL-6 is suggested to be the most important cytokine modulating the hepatic expression of APPs [84], and studies in IL-6-null mice also reveal it to be important in inflammatory regulation of P450 enzymes and DTs. Downregulation of Cyp1a2, Cyp2a5, and Cyp3a11 [84] and of Ntcp, Oatp1, Mrp3, Mrp2, and Bsep [251] mRNAs during turpentine-induced inflammation was abrogated in IL-6-deficient mice. IL-6-deficiency also blocked the downregulation of Cyp3a11 and 2c29 in mice treated with tuberculosis vaccine, while IL-1 β gene deletion had no effect on Cyp3a11 or 2c29 downregulation in tuberculosis vaccine-treated mice [128]. We recently reported similar evidence for the involvement of IL-6 in the regulation of hepatic Cyp2d9, 3a11, and 3a13, in mice infected with *C. rodentium* [64], although the majority of CYPs were regulated in an IL-6-independent manner. These findings were in sharp contrast to those in the LPS model of inflammation, in which IL-6-null mice exhibited regulation similarly to WT of all the P450 enzymes [84] and DTs [201] that were studied. Similarly in WT, IFN γ -null mice likewise had responses of hepatic P450s to LPS injection [64] similar to WT. Compared to WT, mice deficient in both TNF α receptors also had similar responses of P450 enzymes and activities to LPS [104]. Overall, the above results suggest a functional redundancy of cytokines during LPS-induced inflammation [84], such that the absence of any one will not greatly affect the regulation of DMEs or DTs.

19.13.4 Anti-Cytokine Antibodies and Biologic Drugs

One of the disadvantages of knockout mouse models is the possibility of compensatory mechanism developing over time. An alternative approach is to administer neutralizing antibodies to the cytokine in question. Ling and Jamali used this strategy to demonstrate the importance of TNF α to downregulation of CYP1A and CYP3A proteins. The therapeutic TNF α antibody infliximab partially inhibited the downregulation of these proteins in a rat model of adjuvant arthritis [7]. Similarly, in a different rat model

of rheumatoid arthritis, Ashino *et al.* demonstrated that polyclonal antibodies to IL-6 reversed the downregulation of CYP3A mRNA, protein and activity in the liver [6]. The fact that both TNF α and IL-6 seem to be involved in downregulation of CYP3As in arthritis probably reflects the fact that these cytokines can regulate each other's production. These observations in rats are proof of principle for the DDDIs discussed in Section 19.2.3. One such possible interaction for IL-2 is suggested by the study described in Section 19.13.2

19.14 MECHANISMS OF REGULATION

As described above, proinflammatory cytokines are thought to mediate most of the effects of inflammation on hepatic DME and DTs. Consequently, most mechanistic studies have focused on the effects of individual cytokines. Because cytokines exert enzyme-selective effects on P450 gene products, it is important to recognize that no single common pathway has been identified that is responsible for the downregulation of DMEs and DTs. Different mechanisms are likely to pertain depending on the specific gene and inflammatory stimulus and also on the time point in the response.

19.14.1 Transcriptional Regulation

In rat liver, the transcription of CYP2C11, 3A2, and 2E1 is suppressed to 20%, 30%, and 10% of control, respectively, within 1–2 h of LPS treatment in rats [252]. The swiftness and size of these effects suggest that transcriptional suppression is the primary mechanism for the decline of CYP mRNAs.

During an LPS-induced APR, mediated primarily by LPS and proinflammatory cytokines, the expression and activation states of many hepatic transcription factors change [253]. It must be recognized that the transcription factors that predominate in basal and drug-induced expression of DMEs and DTs are different, and that therefore the mechanisms of transcriptional downregulation will also be different between the two states [221].

The transcription factor NF- κ B, a major regulator of inflammation, can be activated by many stimuli including cytokines via their receptor-associated kinases [254], viruses, oxidative stress, and chemical agents [255,256]. NF- κ B has been implicated in the regulation of P450s via several different effects on their induction mechanisms [256,257]. The first mechanism is that NF- κ B can regulate NR-mediated, inducible DME gene expression indirectly by suppressing expression of NRs and/or modulating their binding partner (e.g., RXR). For example, hepatic CAR and RXR expression is repressed in LPS-treated mouse liver [258], and IL-6 stimulation causes a reduction of PXR expression in primary human hepatocytes [259]. IL-1 β decreases CAR expression and decreases phenobarbital-mediated induction of CYP2B6, CYP2C9, CYP3A4, UGT1A1, GSTA1, GSTA2, and SLC21A6 messenger RNA through chromatin remodeling by glucocorticoid receptor (GR)/NF- κ B interaction [260]. NF- κ B can interact with GR, PPAR, RXR, or farnesoid X receptor (FXR) [256].

The NF- κ B pathway can also interact directly with NRs governing DMEs and DT expression [256,257]. Thus, inflammatory stimuli can suppress the induction of CYP3A4 by binding of the NF- κ B p65 subunit to RXR, inhibiting PXR-RXR binding

to CYP3A4 promoter [261]. Inflammatory stimuli can regulate aryl hydrocarbon receptor (AhR) regulated genes (*CYP1A1*, *IA2*, and *1B1*). NF- κ B binds to AhR, and these two transcription factors can mutually repress each other's functions [262].

We found that NF- κ B plays a role in the downregulation of CYP2C11 in rat hepatocytes in response to LPS or IL-1 β , through direct binding to a negative response element spanning the transcription start site of the *CYP2C11* gene [263]. NF- κ B binding can also be identified to the promoter regions of the *CYP1A1*, *CYP2B1/2*, *CYP2C11*, and *CYP2D5* genes by electrophoretic mobility shift assay (EMSA) [256], although this binding has not been shown to be functional.

IL-6 causes a moderate induction of the mRNA of the transcription factor CCAAT-enhancer binding protein- β (C/EBP β , enriched in liver). However, a marked increase in the translation of a C/EBP β isoform lacking a transactivation domain resulted in downregulation of CYP3A4 mRNA in hepatoma cells [264]. C/EBP binding to the promoter regions of CYP2D5 and CYP2B1 measured by EMSA is increased by LPS-induced CNS inflammation, suggesting that C/EBP could negatively regulate the gene expression of CYP2B1 and 2D5 [265].

Hepatocyte nuclear factors (HNFs) regulate the basal transcription of many CYP genes, and many of these factors are downregulated in inflammation [253]. DNA binding activities of HNF1 α , HNF3 β , and HNF4 α are all rapidly suppressed in the rat liver following LPS treatment [252]. Therefore, it is likely that downregulation of HNF expression or activities during inflammation could contribute to the regulation of DME and DT expression [221]. Downregulation of HNF1 α by LPS administration appears to contribute to the downregulations of CYP27A [266], NTCP [267], and OATP4 [268].

The question of whether downregulation or antagonism of NRs responsible for the induction of DMEs and DTs is also a mechanism for the downregulation of basal DME and DT expression is still open to debate. On the one hand, the phenotypes of PXR and CAR-knockout mice suggest little importance of these receptors in basal DME expression. In agreement with this idea, we found that LPS treatment downregulates hepatic P450 expression to a similar extent in PPAR α or PXR-null mice compared to WT [83], indicating that downregulation of P450 during inflammation does not require PPAR α and PXR. On the other hand, siRNA-mediated knockdown of PXR attenuates downregulation of CYP3A4 in human hepatocytes [269]. This could reflect a species difference in the role of PXR in basal P450 expression.

19.14.2 Posttranscriptional Regulation

As detailed in a previous review [219], there is an abundance of kinetic evidence that posttranscriptional mechanisms such as regulation of RNA degradation, protein synthesis, and protein degradation also function in the inflammatory regulation of DMEs and DTs. As a recent example, hepatic CYP2E1 mRNA was rapidly induced in the livers of rats treated with LPS via the i.p. or i.c.v. routes, and this induction persisted for 24 h, during which period the CYP2E1 protein was downregulated [140]. The mechanism of this posttranscriptional regulation is not clear.

Nitric oxide (NO) is a short-lived free radical produced during inflammatory and infectious conditions. We have shown that in cultured hepatocytes, NO formed by inducible nitric oxide synthase in response to an inflammatory stimulus causes a post-transcriptional downregulation of rat CYP2B [270] and CYP3A [271], as well as human CYP2B6 proteins [272]. For the rat CYP2B and CYP3A enzymes this is due to

increased proteasomal degradation of the enzymes [271]. In addition, NO can inhibit the activities of P450 enzymes by coordination to the P450 heme [221]. The *in vivo* relevance of these NO-dependent mechanisms has yet to be established.

19.15 CONCLUSIONS AND FUTURE PERSPECTIVES

The data from animal studies and the limited experiments in humans demonstrate that drug metabolism and transport can be profoundly affected in either direction in inflammatory disease states, and crucially, that this regulation depends on both the nature of the disease/inflammatory stimulus as well as on the specific protein in question. Much more research is needed into the regulation of DMEs and DTs in humans in specific inflammatory disease states, including diseases such as diabetes that have a chronic inflammatory component, and also into identification of biomarkers that can predict these changes. This will require not only clinical research in humans, but also mechanistic research in animal and cell culture models to identify blood-borne mediators, receptors, and signaling mechanisms involved. The effects of many cytokines on drug metabolism and transport have yet to be studied, as have the roles of noncytokine mediators and NLRs.

1.1 SUMMARY

Bioanalysis (BA) in a drug metabolism environment can be defined as the analytical techniques that are utilized to assay various samples that are the result of *in vitro* or *in vivo* studies of one or more new chemical entities (NCEs). BA has continued to evolve in response to the needs of the drug discovery and drug development teams as well as the continuing improvement of the analytical technology that is used for the various assays. This chapter provides an overview of the various assays that are commonly used in various stages of drug discovery and drug development. The chapter is divided into three main sections: bioanalytical strategies, *in vitro* assays, and *in vivo* assays.

For most of the assays discussed in this chapter, the analytical tool is high performance liquid chromatography (HPLC) combined with tandem mass spectrometry (MS/MS). HPLC-MS/MS is preferred because it provides excellent selectivity and is applicable to most small molecules. The strategy for how best to use HPLC-MS/MS for the different *in vitro* and *in vivo* assays is still a topic of debate within the bioanalytical community.

It is common to have different levels of analytical acceptance criteria that become stricter as one moves from the early lead optimization arena and moves into the development arena. Using this strategy, the higher throughput assays that are used in the

screening stage would have minimal standards needed as part of the assay. This makes sense because these assays usually are used for many compounds with only a small number of samples per compound. As one goes to the higher levels, relatively smaller numbers of compounds are being assayed and the number of samples per compound is higher. So, for the higher level assays, it makes sense to increase the number of standards that are required to perform the assay.

There are multiple *in vitro* assays that are used for drug discovery screening of NCEs. The basic strategy for utilizing these various *in vitro* assays is to use them to screen NCEs in order to select those that have druglike properties. These tests are commonly used as part of the absorption, distribution, metabolism, and excretion (ADME) optimization phase of new drug discovery. The most commonly used assays are designed to measure one of the following parameters: permeability, metabolic stability, enzyme inhibition, or metabolism. Each of these assay types is described in this chapter as a subtopic.

In a drug discovery setting, *in vivo* assays are similar to *in vitro* assays in terms of the need for providing the results in a timely manner. The main difference between *in vitro* and *in vivo* assays is that *in vivo* assays are often more challenging because the sample matrix is more complex. Most *in vivo assays* rely on some form of HPLC-MS/MS for the analytical step. The main topics covered in this chapter are: pharmacokinetic (PK) screening, PK studies, and metabolite identification.

In conclusion, mass spectrometry is used throughout new drug discovery and drug development for multiple assays. The type of mass spectrometer that is used depends on the type of assay that is being performed. As mass spectrometers evolve and are improved, it can be safely predicted that they will continue to be the premier analytical tool for many of the assays that are performed at various steps in this process.

1.2 INTRODUCTION

BA in a drug metabolism environment can be defined as the analytical techniques that are utilized to assay various samples that are the result of *in vitro* or *in vivo* studies of one or more NCEs. BA has continued to evolve in response to the needs of the drug discovery and drug development teams as well as the continuing improvement of the analytical technology that is used for the various assays. As shown in Fig. 1.1, BA can be considered the cornerstone for the whole drug discovery process. Multiple review articles and book chapters have been published on the topic of BA used in a drug metabolism environment, and the reader may want to consult these in order to gain additional perspectives on this topic [1–14]. For a comprehensive review of all of these assays, one could also consult the book by Kerns and Di [15].

As shown in Fig. 1.1, lead optimization is a critical step in the drug discovery process. One of the goals of the lead optimization step is to improve the drug metabolism and pharmacokinetic (DMPK) properties of the initial lead compounds in order to find new compounds that are active in the pharmacological model and have acceptable DMPK properties. In order to improve DMPK properties, hundreds of NCEs are tested in various *in vitro* assays. The goal of these studies is to find compounds that can be predicted to have human DMPK properties that are acceptable for the proposed use of the compound [14–21].

Figure 1.1 Schematic showing the various stages of new drug discovery and development as well as how bioanalysis (BA) is the cornerstone to the whole process.

This chapter provides an overview of the various assays that are commonly used in various stages of drug discovery and drug development. The chapter is divided into three main sections: bioanalytical strategies, *in vitro* assays, and *in vivo* assays. The chapter concludes with a summary that serves as a condensed version of the topic.

1.3 BIOANALYTICAL STRATEGIES

For most of the assays discussed in this chapter, the analytical tool is HPLC combined with MS/MS. HPLC-MS/MS is preferred because it provides excellent selectivity and is applicable to most small molecules [5,6,13,14,22–25]. The strategy for how best to use HPLC-MS/MS for the different *in vitro* and *in vivo* assays is still a topic of debate within the bioanalytical community.

It is common to have different levels of analytical acceptance criteria that become stricter as one moves from the early lead optimization arena and moves into the development arena. Table 1.1 shows how this type of strategy might be utilized.

Using this strategy, the higher throughput assays that are used in the screening stage would have minimal standards needed as part of the assay. This makes sense because these assays usually are used for many compounds with only a small number of samples per compound. As one goes to the higher levels, relatively smaller numbers of compounds are being assayed and the number of samples per compound is higher. So, for the higher level assays, it makes sense to increase the number of standards that are required to perform the assay.

1.4 IN VITRO ASSAYS

There are multiple *in vitro* assays that are used for drug discovery screening of NCEs [7,21,26–29]. The basic strategy for utilizing these various *in vitro* assays is to use them to screen NCEs in order to select those that have druglike properties [21,30–34]. These tests are commonly used as part of the ADME optimization phase of new drug discovery [14,35–37]. The most commonly used assays are designed to measure one

of the following parameters: permeability, metabolic stability, enzyme inhibition, or metabolism. Each of these assay types is described in this section as a subtopic.

1.4.1 Permeability

The goal of the various permeability assays is to measure the ability of a compound to cross a cell membrane. This is an important characteristic of a druglike molecule that could be developed into an orally dosed drug. In order for an orally dosed drug to be effective, it must be absorbed across the intestinal gut membrane. The various permeability assays strive to measure the potential for a compound to be absorbed.

The first cell-based assay for permeability measurement is the Caco-2 assay [38]. The Caco-2 cell line is an immortal human colon carcinoma cell line that was commercialized for this assay. It is available in multiple formats, but each of these shares the same functional design. The experimental setup includes a chamber with two sides (apical and basolateral) that contain liquid and are separated by the cell membrane. The test compound can be added to either side. Once the experiment is completed, a sample of the liquid from each side is taken and assayed for the test compound.

The assay is typically performed using HPLC-MS/MS. Various HPLC-MS/MS procedures have been described in the literature [39–48]. Because the goal of the assay is to measure the ratio of the test compound concentrations of the two compartments, in some cases the HPLC-MS/MS analysis merely provides a response level for each compartment; the ratio of the response levels is equal to the ratio of the compound concentrations of the two compartments [49].

In addition to being used as a drug discovery screen, the Caco-2 assay has also been validated as an *in vitro* assay for development compounds to assess their potential to act as either substrates or inhibitors of P-glycoprotein (P-gp) [50]. When used in this manner, compounds are subjected to “bidirectional” Caco-2 assays, in which the test compound is added to the apical side and basolateral side in separate experiments. This test measures the efflux ratio for the compound to determine if it is a substrate for

P-gp. Additional measurements can then be made with known model compounds to determine if the test compound is an inhibitor of P-gp. These results are then suitable to be included in regulatory submission documents.

Another permeability assay is the parallel artificial membrane permeability assay (PAMPA). The advantage of PAMPA is that the artificial membrane is simple to maintain and the assay can be performed using either HPLC-ultraviolet (UV) detection or even a UV plate reader [15]. The main disadvantage of PAMPA is that it measures only passive diffusion (there is no P-gp component as there is with Caco-2). Some drug discovery practitioners have suggested using PAMPA as an initial screen for permeability and waiting until the end of the lead optimization stage to use the Caco-2 cell assay [51].

1.4.2 Metabolic Stability

The goal for the metabolic stability assay is to measure the metabolic liabilities of a test compound. The two most common metabolic stability assays are based on either liver microsomes or hepatocytes. The advantage of using liver microsomes is that they are relatively inexpensive. The disadvantage of liver microsomes is that they only demonstrate phase I (CYP-mediated) metabolites unless additional cofactors are added to allow for phase II (conjugated) metabolism. The disadvantage of hepatocytes is that they are relatively expensive. The advantage of hepatocytes is that they are able to produce both phases I and II metabolites. In some cases, liver microsomes are used as an early screen for metabolic stability and hepatocytes are reserved for those compounds that are potential candidates for development.

Regardless of the microsomal stability process that is chosen, the bioanalytical challenge is the same. For a higher throughput metabolic stability assay, one might need to develop HPLC-MS/MS assays for 100–200 NCEs per week. Typically, this requires automated MS/MS method development software tools in order to meet this analytical challenge. Currently, most vendors for triple quadrupole MS/MS systems will include this type of software in their system. Kieltyka *et al.* [52] have described the utility of QuickQuan™ (Thermo) for the automated MS/MS method development of 500 compounds per month in order to use HPLC-MS/MS to assay these NCEs for metabolic stability. In their application, the compounds were tested in human, rat, and mouse microsomes for metabolic stability. They reported a success rate of >95% when using the automated method development procedure on more than 25,000 compounds.

1.4.3 Enzyme Inhibition

The goal of enzyme inhibition assays is to estimate the potential for a compound to produce drug–drug interactions due to enzyme inhibition in a clinical setting. The assays used for this screen are based on testing the effect of the NCE on cytochrome P450 (CYP) activity by monitoring various well-known CYP substrates. There are a small number of CYP isozymes that account for most of the CYP activity. For example, 50% of all drugs are metabolized by CYP3A4 and 30% of all drugs are metabolized by CYP2D6 [15]. If an NCE was found to significantly inhibit CYP3A4 or CYP2D6 at concentrations in the 1–10 μ M range that could be a potential development issue for that NCE.

There are two common strategies for screening NCEs for their enzyme inhibition potential. The first strategy uses recombinant CYP isozymes and fluorogenic probe substrates. The assay readout is based on a fluorescence plate reader. The advantage of this assay is that it is high throughput and relatively low cost. The second strategy (considered the “gold standard” assay) is based on human liver microsomes (HLMs) and various probe substrates. The assay for this method is normally based on HPLC-MS/MS. Bell *et al.* [53] compared these two strategies and found that for NCEs, the fluorescence-based assay often produced results that did not correlate well with the HPLC-MS/MS-based assay.

Multiple authors have described procedures for assaying enzyme inhibition potential using HLMs with various probe substrates and an HPLC-MS/MS assay [54–62]. The main differences in these assays are: (i) how many probe substrates are measured and (ii) what methodology was used for the HPLC-MS/MS assay. Chu *et al.* [59] described a 0.5 min HPLC-MS/MS assay that was able to provide enzyme inhibition potential results for CYP3A4 and CYP2D6. Plumb *et al.* [60] made use of ultra-performance liquid chromatography (UPLC) combined with MS/MS to assay six probe substrates in 0.5 min.

1.4.4 Protein Binding

Protein binding is another *in vitro* assay that relies on HPLC-MS/MS for the analytical step. The goal of the assay is to measure the free (unbound) concentration of an NCE when it is in human or laboratory animal plasma. Various methods for performing the protein binding experiment have been described [15,63,64]. The typical current strategy for screening NCEs for protein binding is based on 96-well equilibrium dialysis [63,65]. Owing to the fact that many compounds are >99.5% bound, it is important to be able to measure the low concentration of the test compound in the free fraction in these studies. Owing to the low concentrations of some of these samples, it is important to use HPLC-MS/MS for the analytical step. Wan and Rehnberg [66] reported the use of a sample pooling approach for higher throughput screening of protein binding in a discovery setting: their assay was based on HPLC-MS/MS.

1.4.5 *In Vitro* Metabolite Identification

In vitro metabolism studies are a common part of the lead optimization strategy. In a drug discovery setting, the ability to provide metabolite information to the discovery teams is very helpful to the medicinal chemists. For example, knowing the site of oxidation of a compound that has a short *in vivo* half-life can lead to the synthesis of a new compound where that site is modified in a way that blocks the metabolic site; in some cases, this new compound may have a longer *in vivo* half-life. In another example, the metabolite may be active and have a better *in vivo* PK profile—in this example, the metabolite could become the new lead compound in the discovery program.

Typically, in order to perform an *in vitro* metabolism study, one will incubate the NCE in either liver microsomes or hepatocytes which will produce a sample that contains metabolites of the NCE. Microsomes provide a good picture of phase I metabolites (CYP-mediated reactions) while hepatocytes produce both phases I and II (conjugated) metabolites [25]. Multiple literature reviews and book chapters have been written on methods for performing metabolism studies in various matrices [9,25,27,67–75]. These

Figure 1.2 Schematic showing the multiple types of mass spectrometers that can be used for various BA assays in new drug discovery and development. *Source:* Figure provided by Jerry Pappas from Thermo-Fisher and used with permission. (See color insert.)

methods all rely on some form of HPLC-MS/MS analysis to find the metabolites and then to further characterize them in order to provide at least a partial structural identification.

There are multiple types of mass spectrometers that have been used for various BA assays. Figure 1.2 shows four example MS systems that have been used by various drug metabolism researchers. While various strategies have been used in the past to find the metabolites in the *in vitro* sample, currently, most researchers would use higher mass resolution mass spectrometers plus one or more software filtering tools to simplify the task of determining what metabolites are present in the sample. Most triple quadrupole mass spectrometers are unit mass resolution (not high mass resolution). Unit mass resolution is sufficient to separate a compound that has a mass of 520.4 from a second compound that has a mass of 521.4. A high mass resolution mass spectrometer can separate a compound that has a mass of 521.45 from a second compound that has a mass of 521.46. This capability (high mass resolution) is very helpful in finding metabolites in a complex matrix because most of the endogenous material will not have the same exact mass as the metabolites. Examples of mass spectrometers that have high mass resolution capabilities are quadrupole-time-of-flight (QTOF) MS systems as well as Orbitrap MS systems [76].

In addition, because many of the metabolites will have predictable masses (e.g., +16.0 for the addition of an oxygen atom to the NCE), one can use specialized software tools in conjunction with the high mass resolution mass spectrometers to look for metabolites. An example of this type of software is the “mass defect filter”

software described by Zhu *et al.* [75,77]. This filter takes advantage of the fact that most druglike chemicals have an exact mass that is different from most endogenous materials (even though the nominal mass may be the same).

1.5 *IN VIVO* ASSAYS

In a drug discovery setting, *in vivo* assays are similar to *in vitro* assays in terms of the need for providing the results in a timely manner. The main difference between *in vitro* and *in vivo* assays is that *in vivo* assays are often more challenging because the sample matrix is more complex. Most *in vivo* assays rely on some form of HPLC-MS/MS for the analytical step [5,6,22–24,78].

1.5.1 PK Screening

PK screening refers to higher throughput *in vivo* studies that are designed to differentiate multiple compounds in the lead optimization phase of new drug discovery. Typically, groups of compounds will be tested in a standardized manner in order to rank order them or screen out compounds quickly. Various researchers have proposed different types of PK screening assays; most of these assays are based on a rodent model.

One of the more popular assays for PK screening was based on the concept of using cassette dosing [79–84]. Cassette dosing makes use of the ability of HPLC-MS/MS to analyze multiple compounds in one assay. This ability allowed the researchers to dose multiple compounds into one laboratory animal and then obtain individual concentrations for each compound over a series of time points such that PK parameters such as area under the curve (AUC) or maximum concentration ($C_{\max}$) could be measured for each compound. Cassette dosing has the advantage that it requires fewer laboratory animals than would be needed for the standard individual dosing model. Several pharmaceutical companies found cassette dosing to be useful for screening NCEs. Cassette dosing also has disadvantages. For example, cassette dosing can produce incorrect PK parameters in many cases [85]. Another disadvantage is that the assay takes more effort to develop due to the mixture analysis and the planning has to take into account the possibility that compounds (or their metabolites) could interfere with each other if they are not separated chromatographically and are isobaric.

Korfmacher *et al.* [86] described a methodical PK screening system that was not based on cassette dosing. The method was called *cassette-accelerated rapid rat screen* (CARRS). The described system was based on cassette analysis where groups of six compounds are orally dosed individually into two rats and six time points (0.5, 1, 2, 3, 4, and 6 h) are taken from each rat. The samples are pooled across the two rats, yielding a total of six plasma samples per test compound. The assay used a simple two-point standard curve. The result was that all the samples for one cassette could be placed on one 96-well plate—this allowed for efficiencies in sample preparation and HPLC-MS/MS analysis. Mei *et al.* [87] reported on a retrospective study of the CARRS data and found that it correlated well with standard (“full”) PK studies. In addition, Mei *et al.* reported that CARRS provided a screening efficiency of about 50% (i.e., about one-half of the NCEs tested in CARRS were found to provide such low oral AUC levels that they were eliminated from further consideration as a potential-lead

compound). CARRS has been used successfully as a PK screening tool on over 20,000 compounds.

Liu *et al.* [88] described an oral PK screening model based on mice that they called *snapshot PK*. Their model used two mice per compound and provided an oral AUC value in a systematic manner similar to the CARRS model. The snapshot PK was reported to have a screening efficiency of >80%. In addition, because the snapshot PK model was based on mice, less compound was required for dosing the two animals than what would be needed for a similar screen in rats (e.g., CARRS).

1.5.2 PK Studies

PK studies whether in a discovery setting or in a “bridging to development” study are normally carried out in one of two ways [oral (PO) only or intravenous (IV)/PO]. If one is trying to get a full PK picture of a compound in a laboratory animal, then it would be common to dose one set of animals via PO administration and another set (same species) via intravenous IV administration at a similar dose. By comparing the AUC values of the IV and PO dose, one can obtain the important parameter, percentage bioavailability (F), using the following equation:

$$\%F = \frac{(AUC_{PO} \times Dose_{IV})}{(AUC_{IV} \times Dose_{PO})}$$

where

F = bioavailability

AUC_{PO} = area under the concentration versus time curve after PO dosing

$Dose_{IV}$ = dose for the IV administered compound

AUC_{IV} = area under the concentration versus time curve after IV dosing

$Dose_{PO}$ = dose for the PO administered compound.

In addition, multiple additional PK parameters can be derived from a single PO/IV PK study [7,15,89]. The second common PK study is a single rising dose (SRD) study. In a PO SRD study, several sets of laboratory animals are dosed with the test compound PO, but the dose is increased with each set. This study can be used to determine if the AUC increases with the increasing dose. A well-behaved (from a PK perspective) compound may show an almost linear relationship between dose and AUC, while many compound will show a nonlinear increase in the AUC versus the dose of the test compound.

There are multiple steps involved in the BA of a PK study. As shown in Fig. 1.3, these steps involve alignment and coordination across various specialties in order to obtain the test compound, dose the compound, collect the samples, and assay the samples. All of this needs to be done in a timely manner when working in a lead optimization environment.

Once a compound is in development, various safety studies are performed using laboratory animals (typically rat and dog or monkey). In these studies, it is common to take blood samples to measure the exposure of the test animals to the test compound—this type of study is referred to as *toxicokinetic (TK) study*. For TK studies, one must always use good laboratory practices (GLPs) when assaying the plasma samples from the study [90–94].

Figure 1.3 Schematic showing the various steps that are taken when assaying compounds in a discovery PK setting. *Source:* Figure was reprinted with permission from Korfmacher [5]. (See color insert.)

1.5.3 *In Vivo* Metabolite Identification

Metabolite identification is an important part of both new drug discovery and drug development [95]. During the new drug discovery stage, metabolite identification can be very helpful in guiding medicinal chemists in two ways: (i) by pointing toward the sites of metabolism on the NCEs, medicinal chemists can modify the lead compounds in ways that could block the metabolism; and (ii) in some cases, if the metabolite is active and has favorable PK properties, it may become the new lead compound in the series.

During the developmental stage, it is important to identify all major human metabolites of the test compound as well as its major metabolites in the rodent and large animal species used in the safety studies [96]. The Metabolites in Safety Testing (MIST) guidelines that were issued by the FDA (US Food and Drug Administration) have added a requirement that metabolite testing must be done using samples from studies where the test compound has reached steady state [97–100]. These requirements have mandated that pharmaceutical companies show that they have similar or higher exposure in animal safety studies than clinical studies for not only the test compound, but also for all major metabolites of the test compound [97–100].

Multiple authors have described various techniques for detecting or profiling metabolites during the new drug discovery stage as well as the development stage [1,3,27,68,69,72,74,101–109]. Most of these methods rely on using either a triple

stage quadrupole (TSQ) MS/MS system or a hybrid quadrupole-linear ion trap (QTrap) for detecting the metabolites and then getting product ion spectra that are needed to provide structural identification of the metabolites [72,110–114]. The QTrap MS/MS system has unique advantages that make it uniquely suitable for both quantitative assays as well as metabolite identification studies [111,115].

Higher mass resolution mass spectrometers have become an important tool for metabolite identification studies. The hybrid QTOF mass spectrometer has been used extensively for this purpose [101,116–118]. One major advantage of the QTOF mass spectrometer is that it can be used to obtain both high mass resolution mass spectra as well as high mass resolution product ion spectra of the metabolite.

If one obtains full scan data in a high mass resolution mode, then one can use special software tools to help differentiate the dosed compound and its metabolites from endogenous background materials. One of the software tools that can be used for this purpose is referred to as a *mass defect filter* [68,75,77,119–121]. The mass defect filter takes advantage of the fact that most pharmaceutical test compounds have an accurate mass that is shifted (less than) the exact nominal mass. This shift can be measured using a high mass resolution mass spectrometer and can be used to differentiate the compound and its metabolites from isobaric (same nominal mass) interferences. The mass defect filter is a software tool that makes this capability easy to use when looking for metabolites of a dosed compound. Zhu *et al.* [108,109] has recently described two additional high mass resolution software filters that can be used to help find metabolites when assaying complex biological matrices.

1.6 CONCLUSIONS

Mass spectrometry is used throughout new drug discovery and drug development for multiple assays. The type of mass spectrometer that is used depends on the type of assay that is being performed. As mass spectrometers evolve and are improved, it can be safely predicted that they will continue to be the premier analytical tool for many of the assays that are performed at various steps in this process.

2.1 SUMMARY

Gas chromatography (GC) and liquid chromatography (LC) based mass spectrometric approaches represent some of the most commonly employed and informative approaches available for bioanalytical studies. In targeted analyses, such as in metabolite identification or structural elucidation studies, signals from all other components are intentionally minimized by sample cleanup or by the judicious use of selected ion or reaction monitoring or simply ignored if present and separated from peaks of interest. Chemical derivatization and alternative modes of chromatographic separation, ionization, and detection (positive or negative ion) are also often used to separate and further distinguish molecules of interest from background noise and interferences. Information-dependent product ion scans, precursor ion scans, and neutral loss scans add both flexibility and selectivity to analyses, particularly when used in an iterative

manner, where information from previous runs is incorporated into data-acquisition and data-processing strategies. GC- and LC-coupled mass spectrometry (MS) can also be extremely useful for nonbiased or nontargeted analysis, where all chromatographic peaks, or all peaks above a certain intensity, can be characterized by their mass spectral patterns and GC retention indices, thereby enabling their reliable recognition in further samples [1] or their comparison to nontreated controls. The number of potentially reliable and comparable components can be increased by deconvolution of the spectral information using numerical methods incorporated into automated and optimizable software programs such as the automated mass spectrometry deconvolution and identification system (AMDIS, see Ref. 2 or ACD/IntelliXtract™, and for a review of a variety of spectral deconvolution and componentization software, see Ref. 3). Finally, the most robust techniques applied toward structural elucidation, metabolite identification, or the initial detection of putative biomarkers typically involve instruments with sufficient mass accuracy and resolution to provide possible molecular formula. With these most comprehensive approaches, further advances in software systems for spectral interrogation, information processing, and pattern recognition are still needed in order to more fully avail mass spectral investigations with relevant comparisons and scientifically sound conclusions. Thus, the continued development and application of such analytical approaches using time-of-flight (TOF) or ultrahigh mass resolution instruments appear poised to play a significant role in the future of bioanalytical chemistry, particularly as limitations on data processing and interpretation software are further refined.

2.2 INTRODUCTION

Metabolite identification and structural elucidation studies are often complex and time consuming, requiring chromatographic separation, concentration, and detection using numerous spectroscopic techniques such as MS and nuclear magnetic resonance (NMR) spectroscopy. However, such studies have been greatly facilitated by the availability of improved technologies, including (i) temperature and pressure programmable injection ports coupled to capillary GC columns and GC $\times$ GC separation; (ii) ultraperformance liquid chromatography (UPLC); (iii) in-line flow-through radiochemical detectors; (iv) high field (700 MHz or higher) NMR spectrometers capable of direct and indirect detection methods, pulsed field gradients, and liquid chromatography (LC)-coupled (flow-through) or microprobes to allow detection of most NMR active nuclei; and (v) mass spectrometers capable of providing MS^n , high resolution ($>50,000$), and accurate mass (<5 ppm). Advances in MS instrumentation and chromatographic methods have produced further increases in the sensitivity and selectivity of GC-MS and LC-MS techniques, which further facilitate metabolite identification and structural elucidation. Techniques that have increased or enhanced the signal available from the molecule (ion current) or the mass spectrometer include chemical ionization; the use of high energy dynode detectors; and the use of chemical derivatization to increase electronegativity (as in negative-ion chemical ionization), molecular weight, and/or chromatographic suitability. Similarly, advances have been made in methods to decrease the noise, or background, in a particular sample. Solid-phase extraction systems, negative-ion chemical ionization techniques, and MS/MS are examples of efforts to increase signal-to-noise ratios for given analytes by decreasing interferences. Advances in ionization

techniques are being made at a rapid pace, with improved electrospray ionization (ESI), atmospheric pressure chemical ionization (APCI), and photoionization (PI) sources, for example, showing greater utility in a variety of applications. Finally, hybrid mass spectrometers, such as Q-trap and quadrupole time-of-flight (Q-TOF) systems, offer the additional sensitivity inherent in ion-trap technologies, and ion mobility/TOF mass spectrometers add shape resolution and accurate mass and high mass resolution to the separation potential of analytical methods. In the following sections, the general principles of MS are described, as they are typically applied to GC-MS, LC-MS, and GC-MS/MS or LC-MS/MS to qualitative drug metabolism and bioanalytical studies.

2.3 GAS CHROMATOGRAPHY-MASS SPECTROMETRY

2.3.1 GC-MS Analysis Using Electron Ionization

Electron ionization (EI, also termed electron ejection ionization or electron impact ionization) MS combined with GC is a common method of quantitative and qualitative analysis. It offers the advantages of a relatively simple, reproducible ionization mode, a lower source pressure (less potential for source contamination), and a long history of use in the analysis of pharmaceuticals and drugs of abuse. In this mode of operation, electrons are produced by heating a wire filament that has electric current running through it. The electrons are accelerated and concentrated into a beam traveling in a perpendicular direction to the flow of analytes from the GC column. At around 70 eV, the de Broglie wavelength of the electrons matches the length of common bonds in organic molecules, and energy transfer to organic analyte molecules is maximal, leading to the strongest possible ionization and fragmentation. Under these conditions, about 1 in 1000 analyte molecules in the source is ionized. At lower energies, the interactions between the electrons and the analyte molecules transfer less energy and cause less ionization and fragmentation. At higher energies, the de Broglie wavelength of the electrons becomes smaller than the bond lengths in typical analytes, the molecules then become “transparent” to the electrons, and ionization efficiency decreases [4] and produces considerable fragmentation, resulting in the sample’s ion currents being distributed over a large number of m/z values. The distribution of the sample’s ion currents over a wide m/z range results in decreased sensitivity at any given m/z . If lower energies are used (<20 eV), fragmentation can be decreased, but sample ionization efficiency is also decreased.

2.3.2 GC-MS Analysis Using Chemical Ionization

GC with chemical ionization MS offers some significant advantages in quantitative analyses. When using single-ion monitoring and an appropriate choice of a reagent gas, most drugs are softly ionized, generating ions at only a few m/z values. Thus, the sample’s ion currents are concentrated in fewer m/z . Furthermore, because the ions that are formed in chemical ionization mode are generally of higher mass than the base ion obtained for the same compound in electron ionization mode, there is a less likelihood of interferences from contaminants or matrix (higher masses are more unique in nature than lower masses). Although chemical ionization with some reagent gases, such as ammonia, is more difficult than electron ionization, the use and optimization of most chemical ionization gases have become fairly straightforward.

As previously noted, chemical ionization is typically a lower-energy mechanism than that occurring under standard electron ionization conditions, such that ions are more often formed that allow the identification of the molecular weight of the compound. In chemical ionization sources, these ions are produced by the collision of the analyte with ions of a reagent gas that are present in a large excess in the ion source. Some common reagent gases include methane, ammonia, and isobutane. Electrons entering the source preferentially ionize the more abundant reagent gas. The resulting collisions with other reagent gas molecules create an ionization plasma. With methane as the reagent gas, a variety of reactions occur, including the following:

Under these conditions, there are several mechanisms of ionization that can occur with a molecule (M), including protonation, cationization or adduct formation, hydride abstraction, and electron capture or charge transfer:

Many compounds will accept a proton from a donor species to become ionized, and depending on the choice of the reagent gas, the transfer of the proton can occur readily and with excess energy, or will occur with little excess energy transfer. The greater the difference between the proton affinity of the sample and that of the reagent gas, the greater the energy transfer is to the sample during ionization. The excess energy that is transferred produces an analyte ion in a highly excited vibrational state, above a certain point that can lead the sample ion to fragment through the cleavage of covalent bonds. However, some compounds are not particularly stable to protonation (e.g., carbohydrates) or cannot accept a proton readily (e.g., hydrocarbons). In addition to simple protonation, adduct formation often occurs under GC-coupled chemical ionization conditions. For example, with methane as a reagent gas, positive ions at $M + 17$ $[\text{M} + \text{CH}_5]^+$, $M + 29$ $[\text{M} + \text{C}_2\text{H}_5]^+$, and $M + 41$ $[\text{M} + \text{C}_3\text{H}_5]^+$ are also often seen, which when paired with the $[\text{M} + \text{H}]^+$ ion, provide a relatively clear indication of the molecular weight of the analyte for structural elucidation or metabolite identification studies. It is commonplace to denote $[\text{M} + \text{H}]^+$ and $[\text{M} - \text{H}]^+$ ions as quasimolecular ions since these ions comprise the otherwise intact analyte molecule. In addition to protonation or adduct formation, hydride abstraction reactions also frequently occur under chemical ionization conditions, particularly with hydrocarbons and related compounds, such as 1-decanol, where a prominent $[\text{M} - \text{H}]^+$ ion at m/z 157 is observed, with isobutane as the reagent gas. Finally, in the presence of gases with high ionization potentials, electron-transfer reactions result in the production of a radical cation, as is

produced via electron ionization, but in this case, the radical cation is produced less energetically, resulting in diminished fragmentation.

Chemical ionization processes usually refer to reaction mechanisms that produce positive ions; however, negative-ion chemical ionization processes also exist, which can offer additional selectivity and sensitivity in ion formation and analyte detection. Indeed, negative-ion chemical ionization can dramatically increase the sensitivity of analyte detection in GC-MS applications compared with positive chemical ionization or electron ionization, particularly in compounds with electronegative moieties, such as halogen atoms in the xenobiotic itself; as in benzodiazepines or in chlorinated pesticides; or after corresponding derivatization, as for amphetamines, cannabinoids, or opioids [5]:

While several types of ion–molecule reactions can occur, the most common is proton abstraction as shown above, where the proton affinity of the reactant ions determines the propensity of the proton abstraction process.

2.4 LIQUID CHROMATOGRAPHY-MASS SPECTROMETRY

LC-MS offers the advantage of soft-ionization modes (ESI, PI, laser-assisted photoionization (LAPI), and APCI), allowing the separation and ionization of a wide range of volatile and nonvolatile analytes, including peptides, proteins, and thermally labile compounds. Moreover, because of the robustness of modern LC-MS systems, a high sample throughput is normally achievable. The general procedure for analysis of biological samples differs from that for GC-MS, in that aqueous or water-miscible solvents are normally used to introduce the sample onto the HPLC column. Derivatization of the test chemical is not often necessary during initial experiments, and sometimes, it is possible to inject samples of the filtered biological fluid, fortified with internal standard, directly onto the HPLC column. As with GC-MS, the exact procedures used to acquire LC-MS information depend on the nature of the test chemical, the biological matrix, and the concentration of the test chemical and its metabolites in the matrix.

2.5 SINGLE QUADRUPOLE MASS SPECTROMETRY

In one of the more common instrumental designs used for GC-MS or LC-MS analysis, ions that are formed in the ion source are accelerated into a single quadrupole mass filter. The mechanism of filtering ions by mass and charge in a quadrupole instrument involves superimposing an alternating radio frequency (RF) current on top of a direct current (DC) on pairs of oppositely charged rods and ramping the amplitudes of these RF and DC voltages at a constant RF/DC ratio. In this way, both a high mass and a low mass filter are formed, which can be used in tandem to filter ions with unit mass resolution across a considerable range of mass-to-charge ratios (m/z). Whether operating in electron ionization or chemical ionization modes, most quadrupole detectors are quite capable of filtering positive or negative ions within an m/z range of, typically,

10–1000 or 10–2000. By filtering masses with unit resolution extremely rapidly (on a millisecond time basis), a mass spectrum over the range of, for example, 10–1000 can be obtained in intervals of time that allow for several complete spectra to be obtained over individual eluting peaks from even fairly rapid chromatographic separations, such as those that occur in capillary GC. In this way, components from complex mixtures can be baseline-resolved chromatographically and spectrometrically, such that full scan spectra can be averaged across the peak, baseline-subtracted, and library-searched if warranted. Full scan spectra recorded using either electron or chemical ionization can give information regarding the potential molecular mass of the analytes (Fig. 2.1) and some indication of the presence of functional groups and structural features, information that can be augmented by information acquired after chemical derivatization (as described later in this chapter). In addition to operating in full scan mode, single quadrupole mass spectrometers are also capable of performing selected ion monitoring (SIM). In this mode, the mass spectrometer is set so that it does not spend cycle time monitoring ions that are not formed by an analyte of interest (as it does in scan mode), but focuses on the base ion and/or some other diagnostic ion(s) formed by the analyte under the conditions being employed for ionization and detection. SIM can thus be used to increase the selectivity and sensitivity of the detection of the analyte that, when paired with retention time (and the relative intensity of detected ions if more than one is acquired), also offers further confidence in the appropriate identification and quantification of the material being detected. The accuracy and sensitivity of the technique are often increased by the use of stable isotope-labeled internal standards, which provides control for recovery and serves as a “carrier” to reduce nonspecific loss to glassware and other potential active sites during sample preparation and analysis. If more than one analyte is of interest, the SIM method can be programmed to change the ion(s) being monitored based on the analyte’s elution time from the gas chromatograph, thereby allowing maximal cycle time to be spent in monitoring the ions of interest.

2.6 TRIPLE QUADRUPOLE/TANDEM MASS SPECTROMETRY (MS/MS)

A triple quadrupole mass spectrometer can be thought of as a two-stage mass spectrometer with a collision cell between the two stages. As in a normal mass spectrometer, ions are accelerated into the first quadrupole (Q1). This quadrupole can either allow all ions through by scanning by mass or act as a mass filter, allowing only those ions with a specific mass-to-charge ratio to pass into the second quadrupole (Q2). If the second and third quadrupole (Q3) regions allow all masses to pass, a normal mass spectrum is recorded. However, if Q2 is pressurized with an inert gas and used as a strongly

Figure 2.1 Positive electron ionization and ammonia chemical ionization scans of carprofen and its metabolites obtained from the derivatized isolate of a hydrolyzed urine sample from treated canines. Note that while the molecular ions are observed in the electron ionization spectra, in most instances, the ammonia chemical ionization provides further support to the assignment of molecular mass because of the presence of intense protonated molecular ions. *Source:* Reprinted from Dumasia MC, Ginn A, Hyde W, *et al.* Detection and identification of carprofen and its *in vivo* metabolites in greyhound urine by capillary gas chromatography–mass spectrometry. *J Chromatogr B* 2003;788(2):297–307, with permission from Elsevier.

focused collision cell, the “parent” ions allowed to pass through Q1 collide with the gas molecules in the collision cells, causing fragmentation to form “daughter” ions. Variation of the modes of operation of the Q1 and Q3 quadrupole thus provides several modes of MS/MS operation. For example, if Q1 scans and Q3 operates in SIM mode, the mode of operation is called *precursor ion scanning* since the mass spectrometer will reveal all ions that produce a specific daughter ion selected by Q3. This common daughter ion can therefore be used to identify molecules whose structures yield a common fragment or structural motif, for example, looking for peptides whose precursor ions give rise to a daughter ion at m/z 79, indicative of phosphorylation. If the opposite approach is taken, where Q1 is operated in SIM mode and Q3 is set to scan, a product ion scan is recorded. This mode of operation is commonly used to examine a molecular ion for its mass spectrometer fragments to provide structural identification. Another useful mode of operation occurs when both Q1 and Q3 scan at a given mass offset, referred to as a *neutral loss scan*. In this instance, primary ions are being detected that lose the same neutral molecule, such as carbon dioxide or a glucuronide, as the mass of the offset between the two scans is set to 44 or 176, respectively. Finally, when both Q1 and Q3 operate in SIM mode, it is referred to as *single reaction monitoring* (SRM) or *multiple reaction monitoring* (MRM). It is in this mode that a significant increase in signal-to-noise ratio is typically observed with GC-MS/MS compared to GC-MS. This is due to the selectivity of the MS/MS process, which removes the background noise contributed by the matrix; that is, the Q1 quadrupole selects a primary ion characteristic of the compound of interest from other ions that may be present in the matrix, passes it into the collision cell Q2, and uses the Q3 quadrupole to detect one of the characteristic daughter ions of the compound of interest. These two stages of selectivity, ignoring compounds that do not produce the sought-after primary ion and fragment to the selected daughter ion, typically result in a considerable increase in the sensitivity of detection through the elimination of noise and the resultant increase in the signal-to-noise ratio of ion detection. Thus, the SRM mode of operation on triple quadrupole mass spectrometers is one of the most common approaches to the quantitative analysis of trace levels of chemicals in complex matrices.

For metabolite identification studies, full scan, precursor ion, and neutral loss scans are often the most effective means of identifying potential metabolites. In precursor ion scans, it is typical for more than a single fragment ion’s precursor ions to be monitored, corresponding to characteristic fragments from a variety of portions of the parent compound. Thus, in metabolite identification studies, precursor ion scanning experiments are used to identify likely metabolites by determining if they contain an unaltered portion of the parent molecule or an expected alteration, such as hydroxylation. In this approach, the operator needs to know only the fragmentation pattern of the parent ion, not the alteration to the parent compound. However, as alluded to earlier, common alterations to these fragments, such as hydroxylation, may be monitored by looking for precursors of the analyte that give rise to fragments corresponding to the parent fragment plus the metabolic hydroxylation, which are 16 amu higher [7]. In this particular example with nefazodone, the mass spectrum of the parent compound reveals prominent fragment ions at m/z 274 and 246 (Fig. 2.2). These ions, and a fragment ion corresponding to the base fragment ion plus 16 amu at m/z 290, are logical candidates to be used as precursor ions to scan for nefazodone metabolites. In addition to precursor ion scans, neutral loss scans at the corresponding m/z fragments

Figure 2.2 Structure and triple quadrupole product ion spectrum of NEF (m/z 470). The analysis of NEF metabolites in human liver microsomes by triple quadrupole LC/MS is shown in panels (a–f). With permission from the American Society for Pharmacology and Experimental Therapeutics.

of m/z 196, 224, and 212 ($196 + 16$ amu) could also be considered as logical candidates for metabolite identification. As shown in Fig. 2.2, this combined strategy results in several plausible metabolite structures to be detected with a reasonable amount of confidence [8]. Other metabolite specific precursor ion and neutral loss m/z ions can also be useful for metabolite screening. For example, glutathione conjugates are commonly detected under positive ionization conditions by the neutral loss of m/z 129 (loss of the pyroglutamic acid moiety from glutathione) and in negative precursor ion scanning by the loss of m/z 272 (deprotonated γ -glutamyl-dehydroalanyl-glycine from glutathione) and 254 (the dehydrated form of m/z 272) [9].

2.7 ION-TRAP MASS SPECTROMETRY (MSⁿ)

In an ion-trap mass spectrometer, an electrostatic ion gate pulses ions into a 2D or 3D ion trap, as opposed to continuous “beam” instruments such as quadrupoles, where ions continually enter the mass analyzer. For improved performance characteristics, the ion trap is typically filled with helium to a pressure of about 1 mtorr. Collisions between trapped ions and helium molecules dampen the kinetic energy of the ions and contract their trajectories toward the center of the ion trap. The time during which ions are allowed into the trap is critical, in that it should maximize signal while minimizing space-charge effects, which can result in an overall reduction in ion-trap performance.

A conventional (3D) ion trap contains three hyperbolic electrodes, consisting of a ring and two endcaps. Trapped ions are further focused toward the center of the trap by the use of an oscillating potential, called the fundamental RF, applied to the ring electrode. This is accomplished by a parabolic potential with a saddle point, inside the trapping volume, where the strength of the restoring force increases as the ion trajectory deviates from the central axis. An ion will be stably trapped depending on the mass and charge of the ion (m/z), the size of the ion trap (r_0), the oscillating frequency of the fundamental RF (Ω), and the amplitudes of the applied DC (U) and RF (V) voltages. The position of the ion within the stability region in the trap can be moved by changing the amplitude of the applied DC and RF voltages. A mass-selective instability mode is utilized for ion ejection. The mass-selective instability mode of operation utilizes no DC voltage but ramps the RF voltages, and in this mode, ion trajectories become unstable in the axial direction (between the endcap electrodes) but remain stable in the radial direction. Ultimately, ions are ejected through holes in the endcap electrode where they can be detected. Additionally, mass-selective ejection can be facilitated because trapped ions of a given m/z oscillate at a frequency known as the secular frequency that is proportional to the angular frequency of the applied signal, ω . To facilitate ejection of an ion of a given m/z , resonance conditions can be induced by matching the frequency of a supplementary potential applied to the endcap electrodes to the secular frequency of the ion. The ion will then absorb energy from the applied field and the trajectory will linearly increase toward the endcap electrodes until the ion is ejected [10].

Recent advances in ion-trap technology have led to the development of linear (2D) ion traps. In a 2D ion trap, the ring electrode is replaced by a multipole, typically a quadrupole. Ions are cooled by collisions with an inert buffer gas and are trapped radially by a quadrupolar field and axially by an electric field applied to the end electrodes. The position of the ion packed along the axis of the trap can be controlled by varying the repelling voltage applied to the end electrodes. A 2D trap offers many advantages over a 3D trap. The linear geometry of a 2D trap results in a larger trapping capacity than a 3D trap. Many more ions can be trapped without experiencing losses due to space-charge effects of the linear trap's larger internal volume and by focusing along the central axis rather than around a point. The lack of an RF field for entering ions to overcome along the ion-injection axis also gives 2D traps a much improved trapping efficiency compared to 3D traps. Ion ejection from a 2D trap can proceed axially through the endcap electrodes or radially through slits in the center rods.

With triple quadrupole mass spectrometers, a continuous beam of ions is transmitted through the instrument, while mass selection and collision-induced dissociation (CID) of the parent ion continuously occur in separate regions of the instrument (Q1 and Q2, respectively), independent of time. The only time-dependent function is the mass analysis of the daughter ions by the second mass analyzer (Q3). Thus, triple quadrupole mass spectrometers are said to be tandem in space. Ion-trap mass spectrometers, on the other hand, are considered to be tandem in time because parent ion selection, CID, and daughter ion mass analysis are implemented by a timing sequence or scan function [11]. The scan function sets both the amplitude of the fundamental and supplementary potentials and the time taken for each step.

The nominal mass range of an ion-trap mass spectrometer is considerably higher than that of a quadrupole instrument but lower than that achievable on a time-of-flight mass spectrometer (TOF-MS). Quadrupole instruments typically have unit mass

resolution throughout the mass range. Perhaps, the biggest strength of the ion trap lies in its ability to perform multiple stages of mass spectrometry (MS^n), unlike a triple quadrupole instrument or a TOF-MS, dramatically increasing the structural information that can be obtained for a given molecule. Quadrupole ion-trap mass spectrometers can also be extremely sensitive.

While an ion trap has the capability for high mass resolution, mass range, sensitivity, and MS^n that translates into versatile performance as a mass spectrometer, there are also limitations to ion-trap technologies that deserve mention. As noted earlier, the dynamic range of ion traps is limited because when there are too many ions in the trap, space-charge effects lead to diminished performance. Automated scans are used to rapidly count the ions before they go into the trap so that the time ions are allowed to enter the trap is dependent on the ion flux. This ensures only a certain number of ions get in. However, diminished dynamic range can be a problem with ion traps when trace elements in particularly dirty matrices are analyzed because the trap fills with both matrix ions and trace sample ions. Another limitation of the ion trap is that the alternate scan modes of triple quadrupole mass spectrometers, such as precursor ion and neutral loss scans, are currently not possible [10].

LC- MS^n techniques are extremely powerful tools for metabolite identification. With ion-trap mass spectrometers, LC- MS^n experiments can be conducted with extremely high sensitivity, so that structural information can be acquired on extremely small amounts of sample. With this type of instrument, an ion with a particular m/z value can be trapped for a fixed length of time in the ion trap, permitting CID to occur and induce fragment ions, while other ions with different m/z values are ejected [11–13] to occur and induce fragment ions. The trapped fragment ions can then be mass-analyzed to generate a product ion spectrum. The product ion spectrum contains structural information that can be used to determine the structure of the ion selected. The sensitivities for the product ion spectra are excellent because nearly 100% CID efficiency is achieved. Subsequently, a product ion from the first MS/MS experiment can be selected for collisional activation dissociation to produce an MS/MS/MS scan and provide additional structural information about the selected ion. This process can be repeated several times. This technique was crucial to the identification of the metabolites of gemfibrozil (Fig. 2.3) [14] and chromium tripicolinate [15].

2.8 HYBRID AND HIGH RESOLUTION MASS SPECTROMETRY

Metabolite identification and structural elucidation have been greatly facilitated by the development of hybrid and high resolution MS systems [e.g., TOF, Fourier transform (FT), and orbitrap mass spectrometers], which allow for the determination of molecular formula and product ion formula with dramatically increased certainty. If coupled with a tandem approach that allows CID and data-dependent scan activity, the specificity of list-dependent acquisition of MS/MS data for predicted metabolites is improved (as described later).

2.8.1 Quadrupole Ion-Trap Mass Spectrometers

Hybrid instrument systems combine different types of mass analyzers in order to incorporate the best performance characteristics of each into a single instrument. One

common combination consists of a quadrupole mass filter followed by an ion trap (Q-IT). By filtering out unwanted ions using a quadrupole mass filter before they enter the trap, space-charge effects within the trap can be greatly reduced, increasing detection sensitivity for analytes of interest from complex matrix solutions. A particularly useful variation of this combination is the addition of a second quadrupole between the source and the ion trap. An instrument such as this can be thought of as a triple quadrupole instrument in which the final quadrupole is replaced by an ion trap. In this setup, the second quadrupole can be used for normal CID experiments, without experiencing any of the low mass fragment discrimination that results from dissociation in an ion trap, while the final stage of fragment analysis benefits from the increased speed and sensitivity of an ion trap compared to a quadrupole. This type of instrument also retains conventional triple quadrupole modes of operation including neutral loss and parent ion scanning.

2.8.2 LTQ-FT and LTQ Orbitrap

The newest forms of hybrid mass spectrometers consist of two sequential ion traps: a linear ion trap followed by either a Fourier transform-ion cyclotron resonance (FT-ICR) analyzer [such as the LTQ-FT (linear trap quadrupole-Fourier transform)] or an orbitrap analyzer (LTQ Orbitrap). One advantage that comes from having a trap as the first mass analyzer is the ability to fragment parent ions with activation techniques other than CID such as electron capture dissociation (ECD) and electron transfer dissociation (ETD). Another advantage of this setup is increased sensitivity. Much like Q-IT instruments, selected transmission of ions from the linear ion trap reduces space-charge effects by reducing the number of unwanted ions entering the second trap. Sensitivity is also increased by the ability to collect and store ions of interest in the first trap for the amount of time it takes to record the FT-ICR or orbitrap spectrum. LTQ-FT instruments

Figure 2.3 APCI LC/MS spectra recorded in negative ionization mode for metabolites of gemfibrozil (GEM, structure shown). (a) Mass spectrum recorded for the isolated metabolite proposed to represent the acyl glucuronide of the parent compound (1-O-GlcUA-GEM). The MS/MS spectra recorded after isolation and fragmentation of the apparent M-H ion at m/z 425 is shown in the bottom panel along with the structure and fragmentation pathways proposed for this metabolite. (b) Mass spectrum recorded for the isolated metabolite proposed to result from the sulfate conjugate of a hydroxylated metabolite of GEM. The MS/MS spectra recorded after isolation and fragmentation of the apparent M-H ion at m/z 345 is shown in the inset, and the structure and fragmentation pathways proposed for this metabolite are also provided. (c) Mass spectrum recorded for the metabolite proposed to be 2',5'-CH₂OH-GEM. The MS/MS spectra recorded after isolation and fragmentation of the apparent M-H ion at m/z 281 is shown in the inset. The structure and fragmentation pathways proposed for this metabolite are also provided. (d) Mass spectrum recorded for the metabolite proposed to be 2',5'-CH₂OH-GEM. The predominant ion detected with APCI/MS analysis of this metabolite was at m/z 455, which is consistent with a glucuronidated metabolite of GEM that had undergone complete oxidation of one of the ring methyl groups to the carboxylic acid. The detection of fragment ions at m/z 279 and 151 also supports this tentative identification (see proposed structure and fragmentation). It is important to note that the structural elucidation of most of the metabolites of GEM required extended characterizations using MS, MS/MS (and MSⁿ), and numerous studies using NMR and 2D NMR [e.g., heteronuclear multiple bond correlation (HMBC) experiments]. For complete information regarding the analysis and structural assignment, see Ref. 14.

were developed first and have greater resolution and mass accuracy than LTQ Orbitrap instruments, but they are also very expensive and require a cryogenically cooled super-conduction magnet, making the more convenient LTQ Orbitrap instruments a popular choice for this type of hybrid system.

2.8.3 Quadrupole Time-of-Flight (Q-TOF) Mass Spectrometers

A Q-TOF mass spectrometer can be thought of as a quadrupole mass filter and a collision cell (often a second quadrupole) added to the front end of a TOF mass spectrometer. This creates a versatile instrument capable of capturing full high resolution accurate mass spectra in both MS and MS/MS operational modes. In MS mode, the quadrupole operates in RF-only mode, transmitting all ions to the TOF analyzer. In MS/MS mode, the quadrupole is set to transmit a particular m/z value (the parent ion of interest), and the TOF analyzer collects the fragment ion spectrum. The selectivity for quantitation is much better on Q-TOF instruments than on triple quadrupole instruments because of the high resolution with which the TOF analyzer can select fragment ions. Q-TOF instruments have historically suffered from poor dynamic range, but recent advances in technology and design have greatly enhanced the dynamic range of newer Q-TOF instruments. Even with the increased dynamic range, when using a Q-TOF for quantitative analysis, care must be taken to fully assess the signal response of calibration solutions containing the analytes of interest over a suitable concentration range.

2.8.4 Ion Mobility Mass Spectrometry

An additional level of separation can be obtained by combining MS with ion mobility spectrometry (IMS) to create IMS-MS (also commonly referred to as *IM-MS* or *IMMS*). IMS separates ions based on their shape and can therefore directly detect differences in 3D structure among species with the same m/z ratio. The principle behind ion mobility is that ions of different shapes travel at different speeds when pulled by an electric field through a cell containing a relatively high pressure of an inert buffer gas. Owing to increased collisions with the gas, larger more extended ions travel slower than more compact ions. The millisecond timescale for mobility separation interfaces nicely with the microsecond timescale of a TOF detector.

In a conventional ion mobility instrument, ions are pulsed into a mobility cell where they are pulled through by a uniform weak electric field, E , and experience frictional drag because of collisions with the buffer gas. The combination of these two forces results in a constant drift velocity, v_D , which is proportional to E [16]:

$$v_D = K E$$

The proportionality constant, K , is the ion's mobility. Measuring the drift velocity at a series of weak field strengths gives an absolute determination of the mobility. Conventional ion mobility suffers from a lack of sensitivity as many ions are lost due to space-charge effects in the trap in front of the mobility cell and to radial diffusion during transmission through the cell. Commercial instruments are available that implement variations on conventional IMS that have increased sensitivity over conventional IMS, at the expense of not being able to measure absolute mobilities. Two

popular commercial variations are traveling wave (T-wave) IMS and field asymmetric ion mobility spectrometry (FAIMS).

In most ion mobility instruments, including a T-wave ion mobility instrument, mobility separation occurs in the collision cell region. In a T-wave instrument, the mobility cell contains an RF ion guide consisting of a series of ring electrodes. A traveling voltage wave is produced by superimposing a DC potential on the RF of one ring electrode, then switching the potential to an adjacent electrode along the ion guide. Larger ions (lower mobilities) experience more collisions with the buffer gas than more compact ions and thus roll back over the top of the voltage wave more often. As a result, it takes more voltage pulses for larger ions to traverse the cell, and therefore, they exit the cell later than ions with higher mobilities. T-wave mobility separation has significant speed and sensitivity advantages over conventional ion mobility separation, but the path that the ions travel and their collision frequencies are not well defined, making it impossible to measure absolute ion mobilities with this method.

FAIMS differs from most other mobility separation techniques, in that it takes place in the source region and operates at atmospheric pressure. In FAIMS, an asymmetric waveform is applied between two electrode plates and alternates between high and low voltages. Ions move toward the plates at rates that are characteristic and mobility dependent. A DC correction voltage (CV) is applied to alter the path of ions with a specific high field to low field mobility ratio, allowing them to traverse the gap between electrodes without striking the plates. Similar to the operation of a quadrupole mass filter, the CV can be scanned to allow ions with different mobilities to exit. The intricacies of FAIMS separation are complex and not well understood. The separation depends not just on the constant low field mobility but on the ratio of the high field and low field mobilities.

The coupling of IMS to MS provides a rapid separation step before MS analysis, which requires no additional time in either sample preparation or analysis. Most metabolic applications of IM-MS rely on differences in relative mobilities rather than on measurement of absolute mobilities, making the commercially available systems well suited for many of their biological applications. For example, IM-MS can greatly simplify analysis of complex mixtures by filtering out unwanted ions before they enter the mass spectrometer [17], increasing signal-to-noise ratio for analyte identification by separating isobaric compounds in mobility space before mass analysis [18] and separating ions into groups based on m/z mobility ratios to screen for specific modifications [19].

Unbiased LC-MS analysis creates a considerable amount of data, and adding IMS makes the data sets even more complicated. However, the technique is sufficiently sensitive and robust enough to tease out important metabolite information. For example, in its simplest application, consider metabolites that are positional isomers of each other and are impossible to differentiate using MS, as they have identical accurate mass and fragmentation profiles. This particular instance has been studied with ondansetron, where three geometric metabolites of ondansetron were analyzed using an ion mobility LC-MS system, and the metabolites' collisional cross sections were calculated. The cross sections were then compared to molecular modeling and calculated data regarding their conformational cross section in order to putatively identify each of the positional isomers of ondansetron, as they were separated by the ion mobility approach [20]. As a further illustration of the potential application of ion mobility to structural analysis of biomolecules or metabolites, it has also been shown that gas-phase chiral separation

and structural characterization can also be accomplished using ion mobility MS when an appropriate chiral selector, such as a (*S*)-(+)-2-butanol or (*R*)-(-)-2-butanol are added into the nitrogen drift gas. Interestingly, one enantiomer of a racemic mixture interacted more favorably with the (*S*)-(+)-2-butanol chiral selector gas, and when the chiral selector gas was switched to (*R*)-(-)-2-butanol, the order of enantiomer elution from the drift cell was reversed, indicating that some form of the Pirkle rule is being satisfied in the gas phase. Since most studies such as these have involved low molecular weight compounds with only one, or few, chiral centers, it remains to be determined how larger molecules with multiple chiral centers might separate in an ion mobility cell.

2.9 DERIVATIZATION REACTIONS TO ASSIST IN METABOLITE IDENTIFICATION USING MASS SPECTROMETRY

Derivatization reactions can serve several purposes in the isolation and identification of metabolites. First, the chromatographic properties of the metabolite can be altered, such that they may facilitate chromatography. Second, the observation that a derivative is or is not formed in a particular reaction indicates the presence or absence of certain functional groups and thus gives insight into the putative structure of the metabolite. Third, derivatization can produce assignable mass spectral changes that further aid in structural assignments of the unknown metabolite.

In principle, any chemical reaction that converts a compound to a product could be considered a derivatization. In practice, the term generally refers to reactions of a functional group (e.g., an alcohol converted to its ester). Alcohols are most commonly esterified or converted to silyl ethers. Esterification may enhance volatility (e.g., acetates, trifluoroacetates), GC detection (e.g., heptafluorobutyrate, pentafluorobenzyl derivatives), or UV or fluorescence measurement for HPLC (e.g., dansylates). Trimethylsilyl (TMS) ethers and other silyl derivatives are used principally to decrease hydrogen bonding and enhance volatility. By the use of appropriate reagents and conditions, it is often possible to distinguish hindered alcohol groups (e.g., tertiary alcohols) from less hindered ones by their reaction with silylating reagents. Amino groups may be acylated or silylated. Acylation, in addition to usually enhancing volatility, also converts a basic group to a neutral group, thereby changing chromatographic properties drastically. Carboxylic acids may be esterified by the use of diazomethane, boron trifluoride/methanol, or HCl/methanol. Phenolic hydroxyls may be methylated (methyl iodide, dimethyl sulfate, sometimes diazomethane). Ketones may be converted to alkyl oximes, dinitrophenylhydrazones, and so on.

It would require several volumes to review all of the possible derivatization reactions and strategies used to facilitate metabolite identification or structural elucidation. However, it is important to emphasize again that in addition to improving the chromatographic or detection characteristics of analytes of interest, derivatization reagents can be quite useful in structural determination, particularly when combined with mass spectral analysis. Derivatives can provide information regarding the number and nature of functional groups, such as alcohols and acids, and, in some instances, the location or the proximity of certain functional groups. In studies of the metabolism of CP-55,940 (a synthetic cannabinoid agonist), TMS derivatives were prepared using both bis(trimethylsilyl)trifluoroacetamide and the deuterated form of this silylation reagent [21]. Five monohydroxylated metabolites were identified, each with molecular ions

detected at m/z 680 with the TMS derivatives and m/z 716 with the deuterated [$^2\text{H}_9$]-TMS derivative (Fig. 2.4). In this instance, the gain of 36 indicated the presence of 4 hydroxyl groups (i.e., the addition of 1 hydroxyl group to the parent compound). Furthermore, relatively intense ions were present that indicated the position of the hydroxylations and demonstrated that the site of hydroxylation for each metabolite was on a different carbon atom of the dimethylheptyl side chain. Thus, in this case, the derivatization reagent increased the volatility of the metabolites, allowing them to be separated by capillary GC; indicated the number of hydroxyl groups present; and directed fragmentation that provided information regarding the position of the hydroxylations on the molecules' 1,1-(dimethyl)heptyl side chain. Although two dihydroxylated metabolites were also identified in this manner, the position of the hydroxyl groups in these metabolites could not be discerned. It was apparent, however, that both hydroxylations had occurred on the dimethylheptyl side chain.

2.10 METABOLITE IDENTIFICATION STRATEGIES USING LC-MS/MS

One powerful application of LC-MS to metabolite identification is afforded by triple quadrupole instruments that can perform information-dependent MS/MS scan experiments. In a typical metabolite identification experiment, an MS (survey) scan is performed and processed to identify ions of interest as each component elutes from an HPLC column (candidates) during a mobile-phase gradient. Data-dependent product ion (MS/MS) scans are then acquired for the most intense ions present. This is performed, once a mass is selected and allowed to enter the second quadrupole region, by rapidly increasing the collisional energy and performing a scan with the third quadrupole to generate a MS/MS fragmentation pattern. Most metabolite identification software packages available for mass spectrometry include methods for managing the acquisition of data based on information received during a previous scan (e.g., information-dependent acquisition), and ion filtering tools, such as time-based or isotope exclusion lists, to minimize improper candidate ion selection for MS/MS analysis. Selection criteria can be set so that product ion scans are acquired for the n th most intense mass. The number of product ion scans per mass can also be specified. A list of ions to be excluded (e.g., known contaminants) can be specified to reduce the acquisition of irrelevant data. Conversely, masses listed on an inclusion table will always have data-dependent acquisition scans performed. As noted previously,

Figure 2.4 Total ion chromatogram (m/z 50–750) and extracted ion current profiles for m/z 117, 131, 145, 159, 173, 121, and 327 recorded for the TMS derivatives of CP-55,940 metabolites formed in mouse liver S-9 microsomal preparations (at left). The background subtracted mass spectra recorded for the nonmetabolized parent compound, CP-55,940, and the metabolites labeled 1–5 in the total ion chromatogram are shown (at middle and right) for their TMS derivatives (spectra designated A) and their deuterated ($^2\text{H}_9$, or D9) TMS derivatives (spectra designated B), with the diagnostic side chain fragmentation ions highlighted. Note how the increase in the mass between the TMS and the D9-TMS derivative of the apparent molecular ion for CP-55,940 from m/z 592 to 619 is 27 mass units, indicating the addition of 3 TMS groups ($\text{D9} \times 3$). In contrast, the 5 metabolites (1–5) reveal a mass difference between the apparent molecular ions of their TMS derivatives and their D9-TMS derivatives of 36, indicating the addition of 4 TMS groups ($\text{D9} \times 4$). It is also apparent in these figures that the fragmentation of the side chain is directed by the location of the hydroxy-TMS ether derivatives. From Ref. 21.

precursor ion or neutral loss scans can be interspersed with total ion scans and data-dependent product ion scans to increase the likelihood of identifying a potential metabolite. Precursor scans look for molecules that, when fragmented, produce a common mass. This can indicate that an unknown is structurally related to the parent molecule or contains a specified structural element of the parent compound. Neutral loss scans can be especially informative when searching for metabolites. A neutral loss scan searches for ions that, when fragmented, lose a defined mass. This type of phenomena is common to glucuronide- and peptide-conjugated molecules. Thus, the combination of a precursor ion scan common to the parent molecule and a neutral loss scan consistent with a metabolic conjugate would strongly indicate a potential metabolite.

The second component of a commonly used metabolite identification approach is data analysis using software processing programs that search an LC-MS/MS run for metabolic mass gains and losses from a user-defined list and the parent compound molecular weight. With this software, one can compare a sample run with a matrix control and exclude native compounds from consideration and future analysis. Potential metabolites are highlighted, and the transformation name is displayed. Furthermore, a correlation score can be generated by comparing the fragmentation pattern of the parent compound with those generated from unknowns. The correlation score represents the degree to which a fragmentation pattern resembles a reference pattern and is based both on the masses of the fragments and on their relative distribution. Ions of potential interest (based on their plausibility of representing transformation products) for which data dependent product ion scans were not generated in the initial run are typically tagged for reanalysis. Towards that end, most commonly used, commercially available metabolite identification software packages automatically create a new acquisition batch and place the tagged ions on a data-dependent acquisition inclusion list. The samples are then reinjected, and fragmentation data are generated for the tagged masses. The operator may also manually select or exclude masses to be included in the reanalysis.

2.11 METABOLITE IDENTIFICATION STRATEGIES EMPLOYING HIGH RESOLUTION AND ACCURATE MASS MEASUREMENT

The utility of high resolution MS for metabolite identification is based on improved performance characteristics that add to its ability to identify or decrease the number of possible empirical formulas. For instance, for a mass measurement of m/z 118 (where C_{0-100} , H_{3-74} , O_{0-4} , and N_{0-15}), there must be no alternative formulas within 34 ppm for unequivocal assignment of the possible empirical formulas. Increasing the mass measurement to m/z 750 (where C_{0-100} , H_{25-110} , O_{0-15} , and N_{0-15}), there are 626 alternative formulas within 5 ppm. If one narrows down the possibilities in elemental composition, the number of alternative formulas can be decreased dramatically. The most important performance parameters in MS for assigning potential empirical formulas are resolution and mass accuracy. As the resolution and accuracy of the instrumentation are increased, the number of possible empirical formulas can be dramatically decreased, such that with a mass of 516 at 1 ppm or lower, the number of possible formulas is reduced to 4 (given the constraints of C_{35-70} , H_{45-100} , N_{8-16} , O_{9-16} , and S_{0-2}).

The benefits of high resolution and mass accuracy extend well beyond the ability to assign putative empirical formulas to precursor and product ions from collision-induced fragmentation. This becomes particularly evident when a high resolution mass

spectrometer is coupled to a state-of-the-art chromatographic system. When UPLC methods are coupled with high resolution and accurate mass systems, interferences and isobaric species can be resolved based on retention time and mass, which greatly assists in the identification and quantitation of metabolites. With certain hybrid mass spectrometers, extremely useful scan functions for metabolite identification can be performed. For example, with Q-TOF systems, these include the aforementioned product ion, precursor ion, and constant neutral loss scans. With high resolution instruments, the scan of the product ions also occurs at high resolution and mass accuracy. These MS experiments have been demonstrated to be among the most informationally rich techniques for structural characterization of metabolites (for review, see Ref. 22).

For metabolite identification, an initial screening method using rapid MS scans combined with information-dependent MS/MS or MSⁿ scans is performed for treated microsomes/supersomes, cells (e.g., hepatocytes), or animals and their untreated controls. When possible, radiochemical and photodiode array detectors are also used to acquire ancillary information. All data from treated and control systems can be queried by automated data analysis packages to facilitate metabolite identification. Data analysis systems and strategies for metabolite identification typically involve determining the exact mass of the parent. Next, transformation tables are generated and incorporated into the metabolite identification software available on most LC-MS/MS systems. These transformation tables allow exact masses to be calculated for most expected phase I and phase II metabolites (Table 2.1), and the user can then automatically identify and generate ion chromatograms for these hypothesized transformations. The most commonly employed metabolite identification software packages are also able to

TABLE 2.1 Transformation Table (Abbreviated)

Biotransformation	Formula Change	Mass Change (Da)	Mass Defect (mDa)
Oxidative debromination	[M + OH-Br]	-61.9183	81.7
Deethylation (O, N, S)	[M-CH ₃ CH]	-28.0313	-31.3
Oxidative dechlorination	[M + OH-Cl]	-17.9661	33.9
Phosphothionate oxidation	[M-S + O]	15.9772	22.8
Demethylation (O, N, S)	[M-CH ₂]	-14.0157	-15.7
Dehydrogenation	[M-2H]	-2.0156	-15.6
Oxidation (alcohol aldehyde)	[M-2H]	-2.0156	-15.6
Oxidative deamination	[M + O-NH ₃]	-1.0316	-31.6
Reduction	[M + 2H]	2.0156	15.6
Hydroxylation	[M + O]	15.9949	-5.1
Epoxidation	[M + O]	15.9949	-5.1
Oxidation (N, S)	[M + O]	15.9949	-5.1
Oxidation (aldehyde carboxylic acid)	[M + O]	15.9949	-5.1

Acetylation	[M + COCH ₂]	42.0101	10.1
Glycine conjugation	[M-OH + C ₂ H ₄ NO ₂]	57.0215	21.5
Sulfation	[M + SO ₃]	79.9568	-43.2
Glucuronidation	[M + C ₆ H ₈ O ₆]	176.0321	32.1
Glutathione conjugation	[M + C ₁₀ H ₁₅ N ₃ O ₆ S]	305.0682	68.2

customize the data analysis parameters with respect to component subtraction, isotope pattern analysis, and mass defect filtering (MDF). The combination of these powerful data mining and spectral correlation processes allows both expected and unpredicted metabolites to be discovered as described in greater detail below.

Several of the available data analysis strategies include methods for component subtraction, which is a relatively simple but powerful method for eliminating chromatographic peaks and ions contained within control samples or solvents from further consideration as metabolites in treated samples. An algorithm compares components found in treated and control samples using retention time, m/z , and composite MS data. Components that are present in both the control and treated samples can automatically be excluded from further analysis, while components that are unique to the treated sample are automatically highlighted for further inspection. This approach can be extended to include UV spectra and radiographic data that can also help confirm MS peaks that are related to the parent drug or present in the control sample. In our laboratory, we have most recently applied this approach to the identification of the metabolites of fluasterone in canines (Fig. 2.5), as part of a research program sponsored by the National Cancer Institute [23].

Figure 2.5 Overlay of total ion chromatograms obtained during analysis extracts of canine feces. The total ion chromatogram observed during analysis of a methanolic extract of feces collected before dosing (light grey dotted line) is overlaid with a total ion chromatogram (dark grey dashed line) and radiochromatogram (solid black line) obtained during analysis of a methanolic extract of feces collected between 8 and 24 h following oral dosing with [^{14}C]fluasterone at 15 mg/kg. Several radiolabeled peaks are apparent that are associated with peaks in the total ion chromatogram recorded after dosing and not before dosing. For further information, see Ref. 23.

Isotopic pattern analysis is also useful in metabolite identification with compounds that contain elements such as bromine and chlorine or that have easily distinguishable isotope patterns that are not common in endogenous metabolites found in body fluids. For example, drugs can be labeled using stable isotopes including ^{13}C , ^2H , and ^{15}N or radiolabeled at high specific activities with ^{14}C and other radioisotopes to facilitate metabolism studies. These unique isotope patterns can be used to efficiently detect drug metabolites using available software algorithms that filter full scan mass spectra based on the changes in mass and relative abundance of these isotopes and automatically display extracted ion chromatograms representing those isotope patterns that indicate potential metabolites. Even with nonisotope-labeled compounds, these approaches to isotope pattern assessment can be extremely useful to weigh possible elemental compositions or to refine the potential empirical formula list. While this approach is possible with both low and high resolution instruments, the application of this method to high resolution data sets can increase the power of filtering dramatically. There are, however, well-recognized caveats to this approach. For example, isotopic labeling can be lost if the label is in a metabolically favored or chemically labile position. Thus, one needs to also use the other available filtering methods and metabolite identification strategies to avoid excluding metabolites that have lost their original isotopic signature.

Mass defect filtering is one of the most powerful approaches for removing endogenous interfering ions from the xenobiotic metabolite ions of interest. The term *mass defect* originates from the observation that only the monoisotopic element ^{12}C has an integer value for atomic mass, that is, 12.000000. Thus, mass defect is a term that refers to the difference between the exact mass of an element (or compound) and its closest integer value (Table 2.2). The term *mass defect filtering* refers to a postacquisition data filtering technique based on the range of the calculated mass defects of the parent drug and its metabolites. For example, metabolite identification research performed in our laboratory for the National Cancer Institute involved the identification of both phase I and phase II metabolites of fluasterone (Table 2.3). One can see that the mass defect

TABLE 2.2 Nominal Mass, Exact Mass, and Mass Defect of Common Elements

	Hydrogen	Carbon	Nitrogen	Oxygen	Fluorine	Sulfur	Chlorine
Nuclide	H	^{12}C	^{14}N	^{16}O	^{19}F	^{32}S	^{35}Cl
Nominal mass	1	12	14	16	19	32	35
Exact mass	1.0078	12.0000	14.0031	15.9949	18.9984	31.9721	34.9689
Mass defect	0.0078	0.0000	0.0031	−0.0051	−0.0016	−0.0279	−0.0311

TABLE 2.3 Fluasterone Metabolites and Their Mass Defects (Abbreviated)

Structure	Empirical Formula	Exact Mass	Mass Defect
Fluasterone	$\text{C}_{19}\text{H}_{27}\text{FO}$	290.204593	—
	$\text{C}_{19}\text{H}_{29}\text{FO}$	292.220243	0.015650
	$\text{C}_{19}\text{H}_{29}\text{FO}_2$	308.215158	0.010565
	$\text{C}_{19}\text{H}_{29}\text{FO}_3$	324.210073	0.005480
	$\text{C}_{25}\text{H}_{37}\text{FO}_8$	484.247246	0.042653
	$\text{C}_{25}\text{H}_{37}\text{FO}_9$	500.242161	0.037568

associated with its metabolites was relatively small because a large portion of the parent compound structure remains unchanged during biotransformation. In these cases, the mass defects of these metabolites lie within a relatively narrow range (in this particular instance, between -0.042653 and 0.005085). On the basis of the molecular weight of the parent compound, estimation can also be made regarding the range of molecular weights in which these metabolites will occur. MDF could then be applied to filter out all ions that fall outside the expected range of molecular weights and those ions that are within the expected molecular weight range but exceed the expected mass defect range. This approach using multiple mass defect filters allows the true power of high resolution and accurate mass methods to be leveraged for metabolite identification. In summary, the MDF approach attempts to discriminate metabolite ions from matrix ions based on the similarity of the mass defect values of a drug and its metabolites. An example of this approach, using multiple mass defect filters, is shown in Fig. 2.6.

It is important to compare the mass defect filter approach to alternative approaches, such as the precursor ion scan or neutral loss scans that are useful in triple quadrupole instruments. As shown for the example of nefazodone in Figs. 2 and 6, the ion filtering and enhanced search capability of the MDF technique, together with the empirical formula information associated with the data, make high resolution LC-MS/MS instruments an extremely powerful platform for the screening and identification of both common and uncommon metabolites. MDF is also a postacquisition approach, and the templates are flexible and can be refined over time as more information becomes available. Clearly, multiple MDF is more effective than single MDF to detect and identify both phase I and II metabolites, and it also allows the detection of metabolites from hydrolysis or N-dealkylation, even when the products from such processes have mass defects that differ significantly from the parent. To be used most effectively, the core structures used as filter templates should incorporate fundamental knowledge with respect to biotransformation pathways in order to predict reasonable core structure templates. In addition, MDF can remove interference ions that have mass defects outside the filter windows, thus having the potential to simplify spectra by removing noise or interference ions [8]. Finally, MDF allows users to use low threshold values during data processing so that metabolites at very low levels can be identified easily. In contrast, the precursor ion and neutral loss scan approaches require a detailed examination of the parent compound's MS and MS/MS spectra, and the most appropriate ions need to be selected before this type of MS analysis. Once these ions are selected, the data set that is acquired is highly specific to those experimental design choices, and if the metabolic modification to the parent compound alters the fragmentation pathways, the metabolite may be inadvertently missed until the analyst makes changes to the MS ion acquisition parameters.

Once likely metabolites are identified, some software allows further confirmation to be afforded by spectral correlation. Spectral correlation algorithms allow MSⁿ data for potential metabolites to be automatically compared against authentic reference standards. In most instances, a correlation score is generated by comparing the fragmentation pattern of the parent compound with that generated from unknowns. The correlation score represents the degree to which a fragmentation pattern resembles a reference pattern and is based both on the masses of the fragments and on their relative distribution. In this particular instance, the correlation algorithm searches for product ion spectral components that are the same in metabolized and unmetabolized drugs (common product ions) or different through a consistent mass shift that indicates

a chemical modification such as a glucuronide adduct. The combination of spectral correlation and accurate mass determination of parent and MSⁿ fragment ions often allows certain metabolite structures to be eliminated from consideration, often leaving only one likely possibility. However, most LC-MS/MS systems have software capable of the automated generation of a second set of dedicated MS/MS methods (based on the information gathered during the initial analyses) to further elucidate or confirm potential metabolites in an iterative process.

3.1 EXECUTIVE SUMMARY

This treatise describes a wide variety of nanoelectrospray ionization (nano-ESI) mass spectrometry experiments that do not employ high performance liquid chromatography (HPLC) or any other separation science on-line before mass spectrometric analysis. This so-called infusion nano-ESI sample introduction would appear to suffer from significant deficiencies in the absence of on-line chromatography, but in fact, rapid, meaningful analytical results may often be obtained from these experiments. As shown with examples herein, there are many cases where a combination of selective preliminary sample preparation can allow complex biological samples to be directly analyzed by infusion nano-ESI mass spectrometry. In certain instances such as with diluted plasma samples, meaningful results may even be obtained without prior sample cleanup.

Although meaningful infusion nano-ESI mass spectrometry (MS) results appear counterintuitive and at odds with modern dogma that HPLC is required with mass spectrometry (LC/MS), there are unique benefits afforded by nano-ESI, where in many cases, infusion sample analysis may provide comparable or faster as well as easier results than that with LC/MS/MS analyses. Nano-ESI performed with liquid flows at or below 100 nL/min exhibits reduced matrix suppression of ionization. In the absence of prior HPLC separation, therefore, endogenous compounds, metabolites, and other potentially interfering compounds can usually contribute to matrix suppression

of ionization for the target analyte(s). However, since nano-ESI suffers less from these suppression issues, one can still obtain meaningful results for all but perhaps trace level components. Nano-ESI performed at these low liquid flows also provides a more uniform response from related compounds such as a parent drug and its metabolites, which can allow semiquantitative analysis in drug discovery without stable isotope or even structural analog internal standards. When infusion analysis of crude, whole samples is possible, there is less risk of discriminating against certain sample components that may be lost in the usual sample preparation procedures. If automated chip-based nano-ESI is performed, sample-to-sample carryover is also eliminated because each sample experiences a virgin flow path en route to the mass spectrometer. For high throughput sample analysis situations such as newborn screening of carnitines as biomarkers for inborn metabolism errors, elimination of the chromatographic process greatly reduces the run time and hence increases the sample throughput. Each of these features offers some benefits for quantitative analysis experiments.

There is also another set of benefits from nano-ESI infusion experiments for qualitative analysis experiments. Extended analysis times provide improved signal-to-noise ratios and higher quality mass spectra from trace level analytes. In particular, when sequential MS/MS experiments are needed, infusion experiments allow ample time for acquiring the requisite data because the sample introduction is continuous rather than dynamic as in the case with the elution of a chromatographic peak. These benefits afford improved data quality for carbohydrate characterization, top-down protein characterization, metabolite characterization, and lipid analysis studies among many others. Finally, the recent application of liquid extraction surface analysis (LESA) of thin tissue samples, for example, provides an automated approach for microsampling of the chemical constituents in selected small regions of tissue organs followed by automated nano-ESI infusion mass spectrometric analysis of the crude extract. This simple, automated experiment can determine the general disposition of a drug and its phase I and II metabolites within the various organs in a thin tissue slice.

This report provides a brief overview of electrospray mass spectrometry with an introduction to nano-ESI along with a variety of applications that suggest some unique analytical merit for this approach in a variety of drug and drug metabolism applications.

3.2 INTRODUCTION TO ELECTROSPRAY IONIZATION

3.2.1 Basic Principles

3.2.1.1 Mechanisms of Electrospray. Electrospray is a process that generates gas-phase ions at atmospheric pressure from chemical entities in solution [1,2]. A compound that is dissolved in a polar or nonpolar solvent may be passed through the capillary path with an applied high voltage (2–5 kV) with either positive or negative polarity to produce gas-phase ions. The liquid will typically be expelled from the exit of the capillary tubing as an aerosol mixture of small charged droplets and vapor. To decrease the initial droplet size, additives that increase the conductivity of the solution (e.g., low molecular weight acids, bases, volatile salts) are customarily added to the solution. Because the eventual gas-phase ion formation requires extensive solvent evaporation, the typical solvents for electrospray ionization are prepared by mixing water with volatile organic compounds (e.g., methanol, acetonitrile (ACN)). The applied voltage

provides a high electric field gradient that produces a charge separation at the surface of the liquid. As a result, the liquid protrudes from the capillary tip in what is known as a *Taylor cone* (Fig. 3.1). The solution that comprises the Taylor cone reaches the Rayleigh limit [3], which is the point at which coulombic repulsion of the surface charge is equal to the surface tension of the solution. At this point, droplets that contain an excess of positive or negative charge detach from the tip of the liquid jet. These droplets move through the atmospheric region occupied by the charged aerosol toward the entrance of the mass spectrometer that is maintained under high vacuum (Fig. 3.1).

These charged droplets generate charged analyte molecules (gas-phase ions) by one of several possible mechanisms [4]. Two competing mechanisms explain how macromolecules become multiply charged in ESI: the charged residue mechanism (CRM) and the ion emission mechanism (IEM) [5]. According to the CRM, the excess charges on ESI droplets are transferred to and remain on macromolecules enclosed within the droplets after solvent evaporation. The charge on a macromolecule is limited by the maximum charge (i.e., the Rayleigh limiting charge) that a droplet similar in size to the macromolecule can contain without undergoing fission. The final gas-phase macromolecular ion results when the last trace of solvent in the microdroplet evaporates leaving a “charged residue.” Conversely, according to IEM theory, analyte ions desorb directly from charged nanodroplets, driven by the high electric field at the droplet surface. The formation of low molecular weight, singly charged ions in ESI has been explained well by the IEM. Whichever mechanism prevails, the ESI process generates gas-phase ions that can be analyzed for mass-to-charge ratio within the mass spectrometer. Amazingly, this process prevails whether the molecules of interest are inorganic ions, small molecule compounds, or macromolecules such as proteins and industrial polymers.

Higher liquid flow electrospray systems can benefit from additional nebulization by an inert gas such as nitrogen, and this process has been called *pneumatically assisted electrospray* or *ion spray* [6]. Additional improvements that facilitate handling higher liquid flows may be achieved with the addition of heat to the sprayer capillary tube and/or the aerosol spray. As the sequence of droplet splitting (fission) and ion evaporation produces gas-phase ions, the flux of ions, gas, and solvent vapor

Figure 3.2 Schematic drawing of a pneumatically assisted electrospray (ion spray) LC/MS interface. *Source:* Reprinted with permission from Advion BioSciences, Inc. Ithaca, NY 14850.

is sampled through the inlet of an atmospheric pressure ionization (API) mass spectrometer via an orifice-desolvation region or a heated capillary inlet. The latter stage aids further removal of solvent and declustering of solvent molecules from the analyte ions. This whole process is called *electrospray ionization*, and when it is coupled with mass spectrometry, it provides an extremely useful and versatile analytical tool across many scientific disciplines.

Figure 3.2 shows a schematic drawing of a typical pneumatically assisted electrospray (ion spray) LC/MS interface, which was commonly used for coupling HPLC with mass spectrometry (LC/MS) [7] in the early commercial versions of API LC/MS systems. More recent versions of the common electrospray LC/MS sprayers employ additional heat as in the Turbo V system of AB SCIEX (Concord, Ontario, Canada), the heated electrospray ionization (HESI) system from ThermoFisher (San Jose, CA) or the “JetStream” system from Agilent (Santa Clara, CA). These systems all facilitate use of the higher HPLC mobile-phase flow rates of 0.2–1.0 mL/min common for routine application of modern LC/MS experiments. The central sprayer capillary carries the total HPLC effluent through the LC/MS interface with an applied electrospray voltage of 2–5 kV with a coaxial flow of heated high velocity nitrogen nebulizing gas and/or an auxiliary heated nitrogen gas directed on the spray aerosol mixture. The sprayer voltage produces charged droplets, while the nebulizing gas facilitates reducing the aerosol droplet size through evaporation and dispersion of the aerosol. The use of a nebulizing gas for electrospray experiments provides improved robustness of the interface, better negative ion performance, and the ability to handle higher mobile-phase flow rates than “pure” electrospray [8].

3.2.1.2 Sensitivity. Electrospray ionization can provide very high sensitivity provided the “chemistry” of the analyte is well suited for the process of forming gas-phase ions from solution. The preferred analytes are compounds that exist as ions in solution, such as quaternary ammonium compounds or phosphonium compounds. Alternatively, amines can be converted to quaternary ammonium ions by protonation or strong acid compounds, which may be deprotonated in solution in the presence of weak base to form stable anions and provide very good sensitivity for negative ion electrospray ionization. The ideal situation for sensitivity is the formation of highly charged and hence polar ions in a relatively nonpolar solvent. In this case, the ion may be more stable in the gas phase than the condensed phase and hence produce very good sensitivity. The compounds that often provide the best sensitivity are thus polar compounds that are strong acids or bases.

The opposite will be the case of a neutral compound, which cannot be readily protonated or deprotonated to form a stable ion in solution. Instead, these neutral compounds may form weak ion adducts with additives placed in solution with them. Common examples of these compounds are neutral steroids, sugars, or carbohydrates and related compounds. These compounds may be converted to ions in solution by forming adducts with charged species such as ammonium ions, alkali metal ions, or electronegative species which may adduct to an electron-rich site on the compound of interest. Thus, electrospray sensitivity is very much a function of the chemistry of the compounds of interest and the “spray solvent” composition used to carry out the electrospray experiment. When LC/MS experiments are conducted, there may be a need for a compromise between adjusting the composition of the mobile phase to achieve the necessary chromatographic separation while still establishing the “solution chemistry” needed to obtain a high sensitivity electrospray response.

3.2.1.3 Matrix Suppression of Ionization. A fundamental issue with electrospray analysis of real-world samples is the potential for simultaneous competition for ionization between the analyte of interest with coexisting high levels of other compounds present in solution [9]. Thus, the ion current response from a trace level compound as a pure substance in just the spray solvent may be very high, for example, in the presence of no matrix effects. However, if there is also present in the spray solvent another interfering compound(s), especially if present at much higher levels, there is likely to be a substantial reduction of the target analyte ion current response because of “matrix suppression” of ionization. In other words, the other compound(s) compete for the electrospray ion current and suppress or (less often) enhance the target analyte ion current response [10]. This most often occurs when complex biological or environmental samples are not sufficiently cleaned up by the sample extraction process and/or the analysis is subjected to very fast, short run time HPLC separations such that incomplete chromatographic separation occurs. In the latter instance, coelution of potentially high levels of endogenous compounds such as phospholipids, bile salts, and so on may cause significant suppression of the target analyte(s) response.

Although this topic of matrix suppression remains an important caution for anyone employing electrospray studies, there are a few things one can do to minimize this problem. The best approach is to provide sufficient sample cleanup that the analyzed sample closely resembles an analytical standard. In practice, this is rarely realized although the use of molecular recognition provided by immunoaffinity extraction, for example, approaches this goal. [11,12]. In addition, improved chromatographic separation efficiency such as that provided by ultra performance liquid chromatography (UPLC) with careful method optimization for optimal chromatography also minimizes matrix suppression of ionization for eluted compounds of interest.

3.2.1.4 Range of Compounds Amenable to Electrospray Ionization. Unfortunately, electrospray ionization does not provide universal detection of all compound types. Although it is particularly useful as mentioned above for polar small and large molecules, it is not well suited for the trace detection of polynuclear aromatic hydrocarbon (PAHs) compounds that lack heteroatom functional groups or certain very high molecular weight industrial polymers. There are some tricks that allow improved detection of lipids and other neutral compounds by doping the spray solvent with alkali metal ions such as lithium [13,14], and it is well known that even trace amounts of sodium or potassium from glass solvent containers will produce adduct

ions with oxygen-containing neutral compounds such as steroids. If none of these tricks work, one is forced to employ other ionization techniques that are amenable to LC/MS such as atmospheric pressure chemical ionization (APCI) [15] or atmospheric pressure photo ionization (APPI) [16].

3.2.2 Effects of High Versus Low Liquid Flow Rates on Electrospray Performance

3.2.2.1 Conventional LC/MS Flow Rates. Historically, analytical HPLC users have employed mobile-phase flow rates ranging from 1 mL/min to as high as 6 mL/min when nonmass spectrometer detectors were used. However, when the early LC/MS experiments were carried out, it quickly became apparent that the MS vacuum system could not handle such high liquid flow rates [17]. In contrast, the earliest analytical electrospray-MS experiments were confined to spray solvent flow rates of only about 5 mL/min, which in the early 1980s did not have an HPLC flow regime analog so that electrospray LC/MS experiments were not practical or even possible; for example, micro- and nano-HPLC techniques were very rare at that time. Efforts soon followed to develop LC/MS capabilities that would accommodate higher HPLC flow rates, which have evolved to routinely allow mobile-phase flow rates ranging from 0.2 to 1.0 mL/min. However, even today, it is generally known that electrospray detection limits tend to be higher (poorer sensitivity) at higher spray flow rates than at lower flows. Performance is also diminished if the mobile phase has a high aqueous content as well as high concentrations of mobile-phase additives such as volatile acids, bases, or other additives used for improvement of chromatographic or ionization performance. Thus, the electrospray LC/MS practitioner must honor a compromise in control of these variables to achieve optimal sensitivity and performance of the LC/MS system.

3.2.2.2 Nanoscale Spray Liquid Flow Rates. In contrast to the trend to achieve LC/MS capabilities with higher HPLC flow rates, in the late 1990s, Wilm and Mann [18] revisited the low liquid flow rate regime which they called *nanoelectrospray ionization* (nano-ESI). This technique employed spray liquid flows in the sub-100 nL/min range where the nano-ESI ionization occurred in the spray plume emanating from a pulled-glass capillary emitter with an inside diameter of only 5–10 μm . Because the liquid flow was so low, this technique produced much smaller droplet sizes and ultimately was demonstrated to provide the potential for higher sensitivity determinations. Later studies by Vouros and others [19–22] have reported reduced matrix suppression of ionization when low nanoliters per minute spray flows are employed, and in more recent work, the normalization of different analyte response under nano-ESI conditions has been reported [23,24]. Further examples of nano-ESI are described later in the chip-based nano-ESI section of this report.

3.3 MODES OF LIQUID INTRODUCTION FOR ELECTROSPRAY IONIZATION

3.3.1 LC/MS Sample Introduction

3.3.1.1 Benefits of the Chromatographic Process. The routine coupling of HPLC and more recently UPLC [25] to mass spectrometry (LC/MS) has now become a routine application employed across a large range of scientific disciplines. The additional

analytical power of “LC/MS” includes the unique merits of tandem mass spectrometry (MS/MS) [26]. When the feature of tandem mass spectrometry is combined with HPLC or UPLC, one has LC/MS/MS. This unique analytical tool or combination of techniques was reported in 1982 [27] and has progressed from what was once a curiosity to what is now considered the “gold standard” of, for example, the pharmaceutical industry, which has thousands of systems in routine use. Once the “interface” issues were satisfactorily addressed with the development of pneumatically assisted electrospray [6] and the heated pneumatic nebulizer interface [7], the benefits afforded by LC/MS and certainly by LC/MS/MS have been difficult to ignore. This pertains because each hyphenation “segment” of LC/MS/MS offers an orthogonal component or different mechanism of separation. This provides unequalled analytical capabilities because of the multiplicative nature of these orthogonal separation mechanism techniques.

HPLC sample introduction techniques allow the separation of complex mixtures containing historically intractable compounds. These include very polar and high molecular weight compounds not amenable to, for example, GC/MS techniques. Thus, with the combination of HPLC chromatographic separation of a vast array of challenging compounds and now the ability to detect, identify, and even quantify them via LC/MS/MS, this technology has become widely accepted in many disciplines. More recent applications have appeared in the food industry as well as the clinical diagnostic laboratories of major health care and service industries. In all instances, it is the combination of the chromatographic separation process on-line with MS or MS/MS that has received the major interest. Therefore, the benefits of directly coupling HPLC techniques with MS should be relatively obvious. The HPLC system provides an on-line separation of a complex mixture and introduces the separated components of the mixture sequentially to the mass spectrometer. The better the HPLC separation, the better we expect the expected results to be. The “perfect” LC/MS analysis of a complex sample mixture would efficiently separate or resolve the analyte(s) of interest from each other as well as all endogenous chemical constituents. In practice, this is rarely achieved because real-world samples are chemically very complex and/or the chromatographic process is not sufficiently effective to separate all the mixture components from each other.

To complicate matters, in today’s world, most LC/MS experiments are done with relatively short run times and with incomplete HPLC separations. Thus, much of the time an observed HPLC peak will in fact be composed of two or more chemical components. therefore, we are often doing “mixture analysis” within a mass spectrometric scan acquisition in spite of the fact that we have conducted an HPLC separation. There is a good reason why we can actually do this! One of the major benefits of MS/MS is its “mixture analysis” capabilities. Cooks *et al.* [26] demonstrated this capability in the early 1980s. By selecting the unique mass-to-charge ratio of the ionized component in a mixture that represents the targeted analyte, this “precursor” ion may be focused into the collision cell of the tandem mass spectrometer where it is subjected to collision-induced dissociation (CID) and fragmented to its family of product ions (Fig. 3.3). The selected precursor ion will likely represent only the target analyte even though it was initially in the presence of other nonisobaric compounds. This effectively provides a unique approach to mixture analysis, which can complement the sometimes incomplete HPLC separation process. It is this “mixture analysis” capability that has helped make LC/MS/MS sample analysis techniques so hugely successful and popular. Since this suggests that a sample may not always need to be single component, or pure sample, it

Figure 3.3 Schematic representation of a collision-induced dissociation (CID) precursor–product ion scan or transition in a tandem triple quadrupole mass spectrometer. *Source:* Reprinted with permission from Advion BioSciences, Inc. Ithaca, NY 14850.

is sometimes possible to analyze these samples without the HPLC separation component of the experiment. Thus, “infusion” sample introduction techniques are addressed in the next section.

3.3.2 Infusion Mass Spectrometry Sample Introduction

3.3.2.1 An Alternative to the Chromatographic Process. Samples may be introduced into a mass spectrometer without HPLC. This of course provides no “chromatography” or the considerable attributes provided by HPLC. Thus, the entire HPLC system (solvent bottles, autosampler, pumps, plumbing, and HPLC column) may be completely set aside and replaced by a simple “infusion” pump or other sample solution delivery system, which steadily introduces a continuous supply of the sample solution to the electrospray emitter that produces the electrospray aerosol of charged droplets and gas-phase ions from the sample. This form of sample introduction has been used for many years as part of the “tuning” process to “preflight” and “tune” the mass spectrometer for optimum performance before performing LC/MS experiments (see below).

3.4 NANO-ESI IONIZATION (NANO-ESI)

3.4.1 Early Infusion Using Pulled-Glass Capillaries

In the mid-1990s, the infusion sample introduction approach was extended to a new paradigm that involved an ~ 1000 -fold reduction in the sample solution flow rate through the electrospray emitter. As noted above, Wilm and Mann [18] were the first to report on the relative merits of infusion nano-ESI, and improvements in our understanding of this technology was provided later by Karas and collaborators [21,28]. In these latter experiments, they employed a pulled-glass capillary nano-ESI emitter that had a very small orifice [2–10 μm inside diameter (i.d.)]. This provided a sustained spray with an applied high voltage in the absence of any external hydrodynamic pumping. It had been known for several years that there were challenges with stabilization of the Taylor cone and formation of an aerosol of droplets with just the use of electric fields under higher liquid flow conditions. To improve on the stabilization of analyte ion currents, one must provide additional forces such as from pneumatic nebulization [6] and/or heat [7] to facilitate droplet formation and thus complement the role of the electric field for droplet charging. When very low liquid flows (nanoflow of liquids)

are employed, the situation is much different. Other forms of external energy to the charged droplets are not required because the electric field is adequate to charge the liquid and produce the aerosol.

As noted above, the early reports by Wilm and Mann employed “pulled capillaries” made from small glass tubes similar to lambda pipettes or melting point capillaries which were drawn out to a tapered tip while being heated in a small flame. Often the tapered capillary would become closed by this process but could be reopened by carefully breaking off the extremity of the pulled tip. The sample to be analyzed was added manually via a syringe into the larger, inlet opening of the tapered capillary, and this device would be mounted very close to the vacuum inlet of the mass spectrometer wherein a self-sustained nano-ESI aerosol would commence with an applied sprayer voltage. Impressive results first began to appear in the mid-1990s [18] from this approach, but some early practitioners experienced difficulties with maintaining a sustained spray due to clogging of the tapered capillary and related issues. However, interest began to develop in this approach especially in the field of protein and peptide characterization where the continuous infusion of limited, small sample volumes provided extended analysis times to interrogate the sample via multiple MS/MS experiments [29]. In addition, improved sensitivity, increased ion current stability, so-called normalized response, and an apparent decrease in matrix effects [19–24, 30] appeared to offer worthwhile benefits because of nano-ESI. An excellent review of nano-ESI developments was reported recently by Covey and Pinto [31] and Marginean *et al.* [32], while a more general review of electrospray fundamentals has been reported by Cech and Enke [33].

Owing to the increasing interest in these nano-ESI techniques, more reliable pulled capillaries became commercially available first by New Objective, Inc. and later by other suppliers (Proxeon BioSystems, Denmark). However, there was still a considerable degree of manual skill associated with using these devices. The tapered flow path followed by the sample from the inlet of the pulled capillary to the exit tip could cause clogging, which sometimes would be irreversible and require repeating the experiment with the installation of a new pulled-capillary emitter. The small spray orifice dimensions of these devices (10–30 μm i.d.) require particle-free samples that can be difficult to achieve with real-world biological samples. Thus, there was relatively slow acceptance of nano-ESI for some time because it was relatively challenging to successfully carry out routine experiments.

More recent developments, however, have provided commercially available tools that help the new user adapt to these. A few years ago, Agilent introduced its “ChipCube” hardware which integrates a microfabricated HPLC column with a nano-ESI emitter. This “chip” is inserted into the ChipCube wherein all electrical and microfluidic connections are made inside the instrument. The user simply uses a relatively conventional autosampler to make sample injections followed by nanoscale LC/MS techniques (Agilent Technologies, Santa Clara, CA). More recently, Waters has introduced its Trizaic microfabricated chip device which also provides an integrated nanoscale HPLC column with a (removable) nano-ESI tip for on-line nano-LC/MS analysis of, for example, dried blood spots (Waters, Milford, MA). Finally, there is also a new glass chip reported by scientists at Eksigent Technologies which has been coupled via a fused silica capillary directly to a pulled-capillary nano-ESI emitter for on-line nano-LC/MS applications (Eksigent Technologies, Dublin, CA). Each of these recent commercial introductions suggests that in time nanoscale techniques

including nano-ESI will grow as the analytical benefits of high sensitivity and related opportunities become more routine.

3.4.2 Chip-Based Nano-ESI

3.4.2.1 The ESI Chip™. In the late 1990s, there was a growing awareness that nano-ESI had some worthwhile merits, but only the more determined scientists were willing to further explore these. At this time, two scientists from Advion working within the Cornell Nanofabrication Facility at Cornell University (Ithaca, NY) developed a microfabricated chip-based device as an alternative to the pulled capillary for nano-ESI [34]. The first-generation ESI Chip™ was a 10×10 array of approximately $5\text{ }\mu\text{m}$ i.d. microfluidic nozzle emitters. The “ESI Chip” was fabricated from a polished $500\text{-}\mu\text{m}$ -thick silicon wafer. This substrate enabled the formation of an inlet feature that could be etched opposite the nozzle exit to form a cylindrical through channel. This allowed for the communication of liquid introduced from the back or inlet side of the chip through the substrate, which could then be sprayed toward the inlet of an API inlet of a mass spectrometer. The introduction of sample to the ESI Chip through channel is accomplished by the seal formed by a polymer-based, conductive pipette tip close coupled around the inlet region of the chip-nozzle region. Figure 3.4 shows a close-up view of the ESI Chip with increasing magnification allowing visualization of the actual nozzle emitter features. Although the first-generation ESI Chip consisted of a 10×10 array of 100 nozzle emitters, this device was soon expanded to a 20×20 array of 400 nozzle emitters. The current version employs sample introduction via a disposable pipette tip which is depicted in Fig. 3.4. The nozzle dimensions are controlled to within a micron such that changes in the i.d. of the nozzle are used to limit the flow rate of liquid for nano-ESI conditions. There are three general categories of ESI chips that differ with respect to nozzle i.d.s. The common dimensions are 2.5, 4.1, and $5.5\text{ }\mu\text{m}$ i.d. which provide liquid flow rates in ranges of 20–40, 60–100, and 100–500 nL/min, respectively.

A unique feature of the ESI Chip is the presence of the nano-ESI counterelectrode integrated into the nozzle structure. This is accomplished using the semiconductor properties of the silicon substrate and a dielectric coating on all surfaces of the chip [35]. This dielectric allows the application of voltage to liquids delivered to the nozzle structure while also applying a separate voltage or a ground to the silicon underlying the dielectric. The application of a voltage difference between the applied fluid and the silicon creates an electric field across the dielectric and the surface surrounding the nozzle when the fluid exits the nozzle. The high field generated by this close geometry produces a Taylor cone that ultimately produces the nano-ESI plume of charged droplets and thence gas-phase ions that are necessary for electrospray mass spectrometry.

3.4.2.2 The TriVersa NanoMate Robot. A critical requirement for employing the ESI Chip for automated nano-ESI applications is the precise alignment of the conductive pipette tip containing the sample with the inlet of the ESI Chip emitter channel that resides within the array of ESI chip nozzles as well as providing proper alignment of the emitter with respect to the API inlet of the mass spectrometer. The NanoMate was the first-generation robot to accomplish this task. This device positioned the chip appropriately near the mass spectrometer inlet while also providing a real-world-to-chip interface for sample introduction. It has been noted that lab-on-a-chip devices would

Figure 3.4 Schematic drawing of how the robotic probe from the TriVersa NanoMate delivers a conductive pipette tip to the inlet of the ESI chip. The upper inset shows the entire ESI chip, while the lower inset shows a magnification of a single microfabricated nano-ESI spray emitter. *Source:* Reprinted with permission from Advion BioSciences, Inc. Ithaca, NY 14850.

seem to have a bright future, but only if we have convenient and effective means of transferring real-world samples to the chip [36]. The NanoMate robotic system accomplished this in a rather simple way by employing a single-use, disposable pipette tip to aliquot individual samples from sequential wells in a multiwell plate followed by delivering that sample solution directly to the rear, inlet feature of an individual nozzle emitter in the ESI chip (Fig. 3.4). The robot holds a 96 or 384 rack of electrically conductive pipette tips and either a 96-well or 384-well plate of samples in solution. The pipette tips are coated with a proprietary material to preclude oxidation of analytes and to facilitate a leak-tight seal between the tip of the pipette and the ESI chip. The robot operates by picking up a new pipette tip with its metal mandrel which communicates with a gastight syringe for sample aspiration from the multiwell sample plate. The device is computer controlled such that it will go to a selected sample well(s) to aspirate some sample and then deliver the sample solution to a particular ESI chip-nozzle inlet. A schematic drawing of this pipette tip–ESI chip interface is shown in Fig. 3.4. When the pipette tip has mated to form a leak-tight seal at the rear, inlet side of the ESI chip, a combination of nitrogen gas pressure (0–0.5 psi) and high voltage (1.2–1.6 kV) are applied to the pipette tip whereupon fluid delivery and nano-ESI commences. The sprayer voltage and gas pressure may be optimized via the Chipsoft software to form a stable nano-ESI spray current. The robot uses a new pipette tip and nozzle emitter for each sample which eliminates any possibility of sample-to-sample carryover or cross contamination. When operated in this manner, this robotic system provides automated nano-ESI infusion of sample solutions, allowing ample acquisition and analysis time for multiple MS or MS/MSⁿ experiments, but in this format, this is done without any on-line chromatographic separation (see below). A later version of this robotic system was developed and called *the TriVersa NanoMate*, which had the additional

features of automated on-line LC-fraction collection-MS as well as on-line LC/MS via an LC coupler to the chip in addition to infusion experiments [37–45].

3.4.3 Attributes and Challenges of Automated of Nano-ESI Infusion Experiments

3.4.3.1 Sensitivity. There are a number of benefits afforded by nanoflow techniques when the liquid flow rate of the sprayed sample solution is reduced substantially below the usual microliter per minute regime. Nanoflow electrospray has taught us that the efficiency of the ionization process improves approximately in proportion to the flow rate reduction. Although the flux of sample molecules entering the API inlet of the mass spectrometer is much lower under nanoflow conditions, the signal per unit time remains constant and detection limits are improved. Enke [46] has also taught us that the improvement in sensitivity under very low liquid flow rate conditions must be due to a greater efficiency in the conversion of the surface excess charge to vapor-phase ions. An additional benefit of this approach is the use of signal-averaging techniques especially in the tandem mass spectrometry mode where the selection of a precursor ion, for example, greatly reduces the chemical noise in these experiments such that ions from chemical noise are not included in the measurement. Thus, multicomponent mixtures of peptides from enzymatic digests of proteins can be analyzed by nano-ESI infusion MS/MS with plenty of “time” to produce high quality mass spectra [31]. In addition, when the available sample is limited, nanoflow infusion of very small volumes (1 μ L) at 50 nL/min can last for 20 min, allowing plenty of time for interrogating the many different components of the sample mixture with multiple MS/MS experiments, and so on. It is worth noting that although “separation” of the sample components is not being afforded by chromatography in such an infusion experiment, another important “separation science,” tandem mass spectrometry, is providing a mass-to-charge separation in the microsecond timescale. This is accomplished by sequentially selecting nonisobaric precursor ions of individual chemical components of a mixture, for example, and subjecting them to CID independent of the other components in the mixture. This “mixture analysis” capability of MS/MS is a very important benefit, which either reduces the need for chromatography or, in some cases, replaces it.

3.4.3.2 Matrix Suppression of Ionization. The importance of matrix effects in electrospray was briefly discussed above. Certainly, it is well known that the presence of other chemical constituents in the electrospray solvent concurrent with the analyte of interest can produce an abnormal effect on the ion current response of the latter [9,10,19, 47–50]. However, there are indicative reports in the literature which suggest that under the lower flow rate conditions of the spray solvent, under nano-ESI conditions, these matrix effects are reduced [19,22]. Thus, Karas *et al.* showed that when a solution of sodiated turanose at 10×10^{-5} M and *n*-octylglucoside at 10×10^{-6} M was sprayed through a pulled-capillary needle at flows ranging from 1000 nL/min to as low as 20 nL/min, a significant reduction of ionization suppression was observed [22]. Thus, the ratio of turanose/octylglucoside increased from about 2 to 13 as the spray solvent flow was reduced to below 50 nL/min. Similarly, Vouros *et al.* [19] reported a reduction in matrix suppression of ionization under LC/MS conditions as the HPLC effluent was split postcolumn such that the spray to the API mass spectrometer was

operated under nano-ESI conditions. In an early report, Enke [46] described a predictive model for matrix and analyte effects in electrospray ionization of single charged ionic analytes. In this paper, Enke [46] suggests that in low flow electrospray experiments, the solution flow rates are up to 1000 times less than conventional electrospray, but the needle spray currents are comparable. Under these conditions, the excess charge (Q) will be as much as 1000 times greater than that for normal electrospray. One would thus predict that the linear operating range would extend to much higher concentrations and greatly reduce the depressive effect of higher electrolyte concentrations; for example, one should observe reduced matrix suppression to ionization.

3.4.3.3 Ion Current Stability. A common deficiency of electrospray ionization that most users do not fully appreciate is the instability of the ion current generated by this technique. Anyone who has ever worked with electron ionization (EI) mass spectrometry knows what a very stable ion current really is. The ion current from a rhenium filament operated in a vacuum of 2×10^{-5} , which is common for most EI GC/MS experiments, is significantly more stable than that from a conventional ion spray or turboionspray LC/MS experiment. This becomes especially relevant under trace quantitative analysis conditions where the precision and accuracy of the chromatographic peak area (or height) measurement is important.

One of the reasons for a more unstable ion current under higher liquid flow electrospray experiments is the challenge associated with rapidly desolvating the relatively large liquid droplets in the spray aerosol. Since we do not observe ion current in electrospray ionization until or unless we generate gas-phase ions, the mechanism(s) of the electrospray process must be known to truly understand why electrospray ion current can display considerable instability under different conditions. An excellent description of the relevant factors has been reported by Marginean *et al.* [32]. In this treatise, these researchers teach us that the charged liquid is ejected from the cone apex as a liquid jet which breaks down into small charged droplets due to varicose wave instabilities developed along its surface. This cone-jet electrospray regime has been shown to be the optimum for many applications [51]. The transitions between “regimes” of operation, induced by changing operating parameters such as voltage, flow rate, spray solvent composition, distance between the spray emitter and the counterelectrode, and others can be sudden and chaotic. As an example, by increasing the spray voltage of a dripping electrospray, chaotic transitions to the pulsating and then to the cone-jet regimes have been observed and labeled a burst and a stable modes, respectively [32]. These and other microscopic features within the electrospray process contribute to ion current instability. Such instability is most prevalent in higher liquid flow rate, gradient LC/MS applications where there are ongoing changes in the spray conditions where it is difficult to remain within a given, optimal spray regime, for example, the cone-jet regime. However, when infusion nano-ESI conditions are maintained, it is a bit more straightforward to maintain constant, low flow spray conditions without changing the spray solvent chemistry. When the cone-jet regime is maintained, one can obtain truly stable ion current conditions employing infusion nano-ESI conditions.

Figure 3.5 compares the ion current signal stability between infusion employing Turboionspray (TIS) and the ESI Chip using a 10-ms selected reaction monitoring (SRM) dwell time for venlafaxine (m/z 278.2 > 58.1) [35]. The ion current signal stabilities measured from 1 min of spray for TIS and the ESI Chip were 15% and 3.4% relative standard deviation (RSD), respectively. These data were obtained with

Figure 3.5 Plot of SRM data points collected every 10 ms using Turbo ion spray (TIS) and the ESI Chip for venlafaxine. See text for experimental details.

a 5 μ M venlafaxine solution at 5 μ L/min mixed with 400 μ L/min of 75% ACN, 27% water, and 0.2% formic acid. This solution was sprayed using the TIS at 450° C while monitoring the venlafaxine SRM transition from m/z 278.2 > 58.1. The nano-ESI data were obtained with a 5 μ M venlafaxine solution at 5 μ L/min mixed with 600 μ L/min of 75% ACN, 25% water, and 0.2% formic acid. This solution was split to deliver 200 nL/min to the ESI Chip while monitoring the venlafaxine SRM transition from m/z 278.2 > 58.1. Data collected every 10 ms resulted in a 15% RSD with TIS and 3.4% RSD with the ESI. From these data, it is clear that when short dwell times are employed, the ESI Chip ion current stability remains much more stable (lower trace in Fig. 3.5) than that of the TIS ion current stability (upper trace in Fig. 3.5). These data demonstrate a beneficial aspect of infusion nano-ESI conditions, in that often the spray ion current can be significantly more stable than it is at much higher spray solvent flow rates. The benefits of this include improved signal-to-noise levels at very low analyte concentrations and improved accuracy and precision for quantitative analyses.

3.4.3.4 Normalized Response. One of the challenges in early drug discovery is acquiring *in vitro* and *in vivo* quantitative information on the parent drug and its possible metabolites from new chemical entities by electrospray LC/MS/MS techniques. In the early stages of drug discovery, stable isotope internal standards are not available, and yet reliable quantitative information is still needed. One approach to this dilemma would be to assume that the electrospray response from the metabolites is the same

as the parent compound [23,30]. If this were true, one might assume that the area (or heights) of the LC/MS chromatographic peak(s) for metabolites are comparable to the parent drug when referenced to a chemical analog or homolog internal standard used to produce a calibration curve based on the parent compound. Ramanathan *et al.* [24] have shown that by maintaining the same spray solvent conditions across a gradient LC/MS run, “response-normalized” results may be obtained under nano-ESI conditions. In their work, one HPLC unit performs the analytical separation, while the other pump adds solvent postcolumn with an exact reverse of the mobile-phase composition such that the final composition entering the nano-ESI source is isocratic throughout the entire HPLC run. The data obtained from four different structural classes of compounds [vicriviroc (VCV), desloratadine (DL), tolbutamide, and cocaine] and their metabolites indicate that by maintaining the solvent composition unchanged across the HPLC run, the influence of the solvent environment on the ionization efficiency is minimized.

This is reinforced by some observations we have made in related infusion nano-ESI studies. Figure 3.6 shows results from an infusion experiment employing the ESI Chip for an equimolar solution containing 10 exp-5M concentrations for each of aspartame, cortisone, and reserpine (unpublished results, Advion BioSciences, Inc). In the first panel, the protonated molecules for these compounds at m/z 295, 361, and 609, respectively, are shown to display unequal relative abundances when sprayed at 50 μ L/min. For example, the protonated molecules for aspartame and cortisone are less than half the abundance of reserpine present at the same concentration. However, when the spray solvent flow is reduced to nano-ESI conditions at 100 nL/min, the protonated molecule ions at m/z 295 and 361 for aspartame and cortisone, respectively, are increased to be nearly the same as for the protonated molecule of reserpine at m/z 609. These results are consistent with the published results of others which suggest that at least in some instances, nano-ESI flow conditions can provide a normalized response for dissimilar compounds when presented at equimolar concentrations.

3.4.3.5 Dynamic Range. Another important aspect of quantitative analysis experiments or the bioanalytical determination of drugs and their metabolites in either drug discovery or drug development with biological samples is the dynamic range of the quantitative SRM LC/MS experiments [52]. Sometimes, the concentration of the drug and/or its metabolites can range from low picograms per milliliter to several micrograms per milliliter [53]. Thus, it would be helpful if the linear dynamic range could span five to six orders of magnitude or more. However, in conventional SRM LC/MS experiments, it is often a struggle to achieve a linear dynamic range of concentrations that span even three orders of magnitude.

A recent report describes the use of chip-based automated nano-ESI bioanalytical determination of reboxetine with a 500,000-fold linear dynamic range in dog plasma using an analog internal standard [54]. The optimal nano-ESI response for reboxetine was observed with 90% ACN/water without mobile-phase modifiers. Infusion SRM data were collected for all samples to generate ion current profiles with a base “infusogram” ion current profile width of ~20 s. Matrix suppression was evaluated and ranged from ~30% to 60% across the different lots and species which were found to be suppressed by similar amounts, suggesting the similarity in ionization properties between the two. A comparison of analyses by nano-ESI-MS/MS and liquid chromatography

Figure 3.6 Infusion of an equimolar 10^{-5} M solution of aspartame, cortisone, and reserpine under two different solution flow rate conditions. The protonated molecules in each experiment are denoted with their respective arrows. See text for experimental details. *Source*: Reprinted with permission from Advion BioSciences, Inc. Ithaca, NY 14850.

coupled to tandem mass spectrometry (LC/MS/MS) showed that nano-ESI-MS/MS had a greater slope for the calibration standard curve compared to LC/MS/MS, indicating greater sensitivity for the former technique. These authors also indicated that the amount of sample infused during nano-ESI-MS/MS was ~ 80 -fold less compared to the amount of sample injected during LC/MS/MS. The absence of carryover (attributed to the lack of a common fluid path) in the nano-ESI infusion technique enabled the

Figure 3.7 Calibration standard curve for reboxetine in dog plasma ranging from 100 pg/mL to 50,000 ng/mL (500,000-fold range). The plot is displayed in log–log scale using power regression with no weighting. *Source:* Reprinted with permission from Wickremsinhe ER, Ackermann BL, Chaudhary A. Validating regulatory-compliant wide dynamic range bioanalytical assays using chip-based nanoelectrospray tandem mass spectrometry. *Rapid Commun Mass Spectrom* 2005;19:47–56.

extension of the assay linear dynamic range to 500,000-fold, and the possibility of analyzing samples in a single batch without the need for reanalysis of samples with high concentrations.

The amount of carryover in typical LC/MS/MS analyses limited the range of the reboxetine assay to 200-fold, thus requiring a second dynamic range assay or analysis following dilution to quantify samples with concentrations above the range. This not only delays the reporting of data but also invariably increases the cost of analyses as well as the amount of documentation required, especially when operating under GLP compliance. In contrast, this report presents data using robotic instrumentation that demonstrates total elimination of system carryover with a dynamic range spanning 30,000-fold for reboxetine, and extendable up to 500,000-fold. A standard curve ranging from 0.1 to 50,000 ng/mL was prepared and analyzed demonstrating the possibility of analyzing samples spanning a dynamic range of 500,000-fold (Fig. 3.7).

3.4.3.6 Conservation of Limited Sample Quantities. Infusion nano-ESI analyses of precious samples provides the opportunity to acquire data from multiple sequential experiments such as MS/MS, MS^n , or K_d studies [55] while consuming very little of the sample. For example, during the course of studying biospecific noncovalent host–guest interactions between a precious target of limited availability with a series of drug candidates, an infusion nano-ESI analysis experiment conducted at 100 nL/min will consume only 2 microliters of sample over an experimental acquisition time of 20 min. Thus, conservation of precious or limited sample quantities may be achieved by this analytical strategy.

3.4.3.7 Signal Averaging. In some instances, LC/MS/MS experiments are conducted in order to identify a trace level analyte. To accomplish this task, a high quality full-scan CID mass spectrum is often required so the analyst can interpret the spectrum for structural characterization. In many cases, the quality of a CID mass spectrum may be compromised due to the low level of the analyte that provides a weak LC/MS/MS signal. This fact coupled with a relatively fast scan rate needed to acquire data across the HPLC peak produces mass spectra with sufficiently weak ion current signals that it may be uncertain which CID mass spectral peaks are real. This problem may be mitigated if the sample analyte can be continuously infused while the mass spectrometer is scanned in a slower, repetitive manner and the ion current signal is “averaged” as is customarily done in extended NMR experiments. This “signal-averaging” approach can produce much higher quality full-scan CID mass spectra for structural characterization.

An example of these described benefits is shown in Fig. 3.8a–c, which shows the infusion full-scan MS/MS mass spectra for a very weak chromatographic peak from the carboxy-ibuprofen-diglucuronide metabolite from the LC/MS/MS analysis and fraction collection of a human urine extract after the administration of ibuprofen [35]. This weak metabolite was fraction collected (see below) during the gradient LC/MS/MS run which provided a CID mass spectrum of insufficient quality for metabolite identification. The collected fraction was subsequently analyzed by nano-ESI infusion using the TriVersa NanoMate and the ESI Chip coupled to a QTOF mass spectrometer system. Figure 3.8a–c shows the infusion MS/MS mass spectra of the protonated molecule at m/z 589.3 of the trace LC fraction for the carboxy-ibuprofen-diglucuronide peak described above. A sequence of full-scan CID acquisitions for 5 s (Fig. 3.8c), 1.8 min (Fig. 3.8b), and 8 min (Fig. 3.8a) shows a dramatic improvement in the signal-to-noise ratio with extended acquisition time as well as mass spectral data quality from these signal-averaging experiments, which may be readily accomplished by nano-ESI infusion of trace fractions collected from an LC/MS/MS experiment. Infusion of this trace LC-collected metabolite enables the acquisition of a high quality MS/MS spectrum by signal averaging the product ion mass spectrum of the precursor ion at m/z 589.3. Infusion of LC fractions can easily improve the signal-to-noise ratio by a factor of 10 when compared to that obtained using on-line LC/MS/MS, and up to 50-fold signal enhancement has been reported [56].

3.4.3.8 Extended Analysis Time for Multiple MS/MS Experiments. Today’s modern mass spectrometer systems provide a wide variety of possible experiments that can be performed while an analyte is being ionized and introduced into the mass analyzers. This includes changing voltages and potentials which are helpful for establishing the

Figure 3.8 Infusion MS/MS of m/z 589.3 of an LC fraction for the carboxy-ibuprofen-diglucuronide peak from an extended analysis time LC separation. (a) sum of 96 scans; (b) sum of 20 scans; (c) single scan. *Source:* Reprinted with permission from Schultz GA, editor. A silicon-based ESI chip with integrated counter electrode and its applications combined with mass spectrometry. Miniaturization and Mass Spectrometry, ed. S. Le Gac and A. van den Berg. 2009, The Royal Society of Chemistry.

optimum sensitivity performance of the system as well as multiple MS/MS experiments to derive additional structural information from a particular chemical compound (see below). As an example, a modern QTRAP system is a triple quadrupole mass spectrometer with a linear ion trap (LIT) feature in Q3. Thus, the conventional tandem quadrupole scan modes are available as well as several high sensitivity ion trap mass spectrometer scans using the final quadrupole as a LIT mass spectrometer. These include an enhanced product ion (EPI) mode, enhanced resolution (ER) mode, and an enhanced MS (EMS) mode, which all benefit from the third quadrupole operating as a LIT. A wide variety of useful experiments may be programmed with this system, but sometimes, it is difficult to complete all of them during the rapid elution of a narrow HPLC peak in the LC/MS/MS mode. When infusion MS is performed, however, there is ample time to perform all the experiments necessary to serve a given need. There are similar benefits when extended analysis time is available for MSⁿ experiments with three-dimensional ion traps and FT-ICR systems. Therefore, infusion experiments are particularly useful to an analyst who wants sufficient extra time to employ the many additional analytical capabilities of a modern mass spectrometer while examining the mass spectral behavior of a particular chemical compound.

3.4.3.9 Selectivity Afforded by High Resolution Mass Spectrometry. Within just the past few years, there has been a renaissance of interest and analytical capabilities with the advent of modern time-of-flight (TOF) mass analyzers[57] as well as orbitrap technology [58]. This capability is a renaissance because high resolution mass spectrometry was available and employed over 40 years ago, albeit not with the facility of modern condensed-phase sample inlet systems [59]. Specifically, this capability provides high resolution mass separation such that isobaric compounds with even very

small mass differences may be resolved and distinguished from each other. In addition, this capability also provides detailed elemental composition information for not only the molecular species but also the series of product ions resulting from MS/MS or other decomposition processes. As such, this complement or possible alternative to MS/MS can provide valuable selectivity for both the detection as well as the identification of unknown compounds. This latter information may be acquired either coupled with on-line separations such as HPLC or via nano-ESI infusion of suitably cleaned up samples as described above. In the latter case, the added selectivity of high resolution mass measurement can make up for the lack of chromatographic separation provided matrix suppression of ionization or other issues do not preclude satisfactory detection of important analytes. A recent review of the merits of high resolution mass spectrometry and accurate mass measurement was recently reported by Brenton and Godfrey [60].

3.4.4 Applications of Nano-ESI Infusion

3.4.4.1 Infusion of Analytical Standards. One of the initial experiments any expert analytical mass spectrometer system operator should perform is to “tune” the ion optics and calibrate the mass axis of the instrument before analyzing samples of interest or those containing unknown analytes. This has been done for many years with GC/MS instruments by opening a valve which permits the continuous introduction of a volatile reference compound into the ion source mass analyzer. This provides a stable, continuous introduction of a sample that has ions of known mass-to-charge ratios and relative abundances that may be used to tune and optimize the mass spectrometer ion source parameters and the ion optics of the system. For volatile samples, a similar approach was used historically for high resolution MS where perfluorokerosene (PFK) was “leaked” into a heated batch inlet as a gaseous reference compound for exact mass measurements[61].

An API mass spectrometer also requires tuning optimization and mass axis calibration which may be similarly done via the infusion of a reference compound solution or mixture of compounds. For the equivalent experiment in today’s electrospray-MS environment, a solution of a reference standard or mixture of chemical compounds is “infused” continuously through an electrospray sprayer device to produce a continuous source of ions from the reference standards. This allows the operator or the “auto-tune” software program to “tune” and optimize the ion optics of the mass spectrometer and calibrate the mass axis with reference to these standard reference compounds. In these experiments, the sample is usually a standard mixture of known compounds as a relatively clean solution free of any levels of endogenous materials. Today’s modern API MS systems are routinely tuned and calibrated with this sample introduction approach wherein an aqueous/organic solvent mixture of the tuning standard sample is introduced to the mass spectrometer via infusion at flows of perhaps 5–10 mL/min. Of course, this approach would be expected to perform optimally with simple mixtures containing appropriate reference compounds whose molecular weights span the mass range of interest.

The chip-based nano-ESI system described above is ideally suited for automation of these experiments. Thus, a known reference sample containing a selected reference compound or mixture of compounds is infused continuously via nano-ESI in either the positive or negative ion mode while the ion source and ion optics are optimized for

sensitivity, mass resolution, and accurate mass assignment under computer-controlled conditions. This may be done manually by a skilled operator or in an automated mode using the appropriate vendor-supplied “autotune” software. Modern mass spectrometer systems are much more stable and dependable than those of the past, but it is still important to monitor the performance of an API MS system on an ongoing basis as the performance may deteriorate due to exposure to dirty samples, high voltage power supply drift, changes in collision gas pressures in the collision cell, humidity in the laboratory environment, and other variables which can affect the performance of these systems. A special application of this capability is described in the next section.

3.4.4.2 Automated Compound Tuning Optimization. A special case of compound tuning described as a semiautomated procedure for this tuning routine was reported in a recent report by King *et al.* This report [62] describes a semiautomated parameter optimization for high throughput MS/MS detection workflows, which include many different chemical compounds of interest. Although it is generally known that each chemical compound may have a slightly different set of tuning parameters, especially the collision energy (CE) for MS/MS experiments, most MS/MS experiments these days are set up with a fixed set of “average” MS/MS experimental conditions, which may in fact discriminate against some of the compounds. In an ideal experiment, one would optimize the instrument operational parameters for each individual compound so as to obtain the best performance for each compound. However, this is very difficult and typically impractical to do during LC/MS/MS experiments since the timescale as chromatographic peaks elute one after another is only a few seconds. This does not leave enough time for optimizing the tuning parameters.

King *et al.* described a semiautomated procedure that involves placing solutions of many different new chemical entities (future drug candidates) into individual wells of a multiwell plate followed by automated nano-ESI infusion of each compound [62]. Each infusion experiment may last several minutes if necessary, which allows plenty of time to optimize the tuning and MS/MS operational parameters for each compound. These tuning parameters may then be stored in the vendor acquisition software and employed in subsequent on-line LC/MS/MS bioanalytical experiments used for the quantitative determination of these compounds in biological samples. Figure 3.9a–d shows the fragment–precursor intensities as a function of CE for different chemical compounds, which include urapidil, reserpine, acetaminophen, and 6- β -hydroxytestosterone. While the ion current intensities do change with CE, the curves for the fragments are relatively broad. A noted exception to this general trend observed in Fig. 3.9a–d is acetaminophen where the CE voltage required for this compound is much lower (Fig. 3.9c). These results show that a small change in CE can significantly affect the response of the m/z 110 fragment ion for this compound. Thus, the ability to automatically infuse a large number of different chemical compounds in a sequential manner allows sufficient time to determine the optimum CE and other tuning parameters for each compound and thus obtain the best mass spectral results for subsequent pharmacokinetic and toxicological studies[62]. These researchers also reported that the optimized tuning conditions provided nearly identical mass spectral results across the three different triple quadrupole models provided by one major vendor.

3.4.4.3 LC/MS/MS with Simultaneous Fraction Collection. In the early days of HPLC and analytical mass spectrometry, researchers “collected fractions” from their

Figure 3.9 Fragment and precursor ion intensity as a function of collision energy (CE). (a) Breakdown curve for urapidil. (b) Breakdown curve for reserpine. (c) Breakdown curve for acetaminophen. (d) Breakdown curve for 6- β -hydroxytestosterone. See text for experimental details. *Source:* Reprinted with permission from Geddes K, *et al.* Semi-automated tandem mass spectrometric (MS/MS) triple quadrupole operating parameter optimization for high-throughput MS/MS detection workflows. *Rapid Commun Mass Spectrom* 2009;23:1303–1312.

HPLC separations and analyzed the individual fractions of collected peaks by direct insertion probe mass spectrometry. This was a tedious procedure, but the valuable information from mass spectrometry made it worth doing. The merits of this information motivated early investigators to explore various ways to accomplish on-line LC/MS and LC/MS/MS techniques. Today, these techniques are ubiquitous and offer a tremendous source of analytical horsepower to researchers across many disciplines. Modern quantitative analyses are performed by LC/MS/MS via SRM experiments that can sample many times across even very narrow UPLC chromatographic peaks, which may be only a few seconds wide at the base. These SRM experiments, however, monitor only one or two precursor–product ion transitions, which can be performed in 5–50 ms. However, for qualitative mass spectral identification of an unknown metabolite or compound, one needs a full-scan CID mass spectrum, which on a triple quadrupole mass spectrometer usually requires one or more seconds to acquire. Also, there are additional meaningful MS/MS experiments such as MS^{*n*} or the summation of multiple scans, which require more time than is often available during the elution of a narrow HPLC or UPLC chromatographic peak.

Today, the mass spectrometric identification of drug metabolites is a common need in the pharmaceutical industry. Although in some cases the full-scan LC/MS/MS analysis

of a biological sample or extract can provide the necessary data for metabolite identification, often the quality of the CID mass spectra is insufficient to provide compound identification. In these instances, it is helpful to have an automated procedure for HPLC or UPLC fraction collection followed by an automated means of analyzing the collected fractions. Hopfgartner *et al.* have reported on the use of the TriVersa NanoMate for providing both of these capabilities [56]. Figure 3.10 shows a schematic drawing of the system. HPLC column dimensions ranging from 4.6 to 0.320 mm i.d. may be used with the effluent split appropriately between the flow needed for chip-based nano-ESI to the mass spectrometer (100–200 nL/min) and the portion split to a multiwell plate for on-line fraction collection (see above). These researchers reported that the longer time frame available, because of the low flow rates of chip-based infusion, allows for the performance of many different types of experiments such as neutral loss, EPI studies, and MS³ and even polarity switching which is possible on the QTRAP mass spectrometer system. Thus, the most meaningful experiments for the relevant fractions can be selected in real time during infusion, which would ordinarily require several reinjections when using only LC/MS techniques. These experiments allow for the post-LC/MS/MS infusion analysis of selected fractions, which may contain metabolites whose structural characterization may be required. The ability to continuously infuse selected fractions while performing a variety of MS/MS experiments with a steady analyte ion current signal can provide improved quality mass spectral data from which structural characterization may be facilitated.

3.4.4.4 Proteomics. There is little doubt that the study of an organism's complete complement of proteins, which is the basis of proteomics, will have a significant impact in all areas of the life sciences in the years to come. This results because to really understand biological processes, we need to understand how proteins function in and around cells since they are the functioning units. In recent years, mass spectrometry has become an important tool for dissecting protein structure and function. Using electrospray ionization and matrix-assisted laser desorption ionization (MALDI)-based approaches, it has been possible to monitor protein folding, characterize noncovalent protein complexes, and assess the contribution of individual amino acid residues to a protein's function.

The task of studying the proteome has its share of challenges [63]. One involves the very high number of proteins that need to be identified. The ~35,000 genes in the human genome can code for at least 10 times as many proteins; in extreme cases, a single gene alone can code for more than 1000. Another challenge is that amino acids, the base units of the peptides that make up proteins, are so small. The analytical challenges involved with fully characterizing the sequence of proteins and very importantly the three-dimensional structure and most importantly the function of proteins are the holy grail of modern molecular chemistry.

In proteomics-based mass spectrometry, the scientist is faced with detecting and identifying minute quantities of one or more potentially unknown biologically important macromolecular compounds. Not only is this a challenge in itself, but it is often necessary to detect minor differences between an individual's healthy versus disease state, differences between male and female sexes, or differences among ethnic groups, and so on. Often, the biological dynamic range can be as high as 10^{12} , while the dynamic range of our measurement tools may be only 10^3 . Thus, a careful combination of sample preparation and high separation efficiency is needed to isolate and characterize potential biological species of interest from the vast array of other biological matrix components.

As an example of the complexity and analytical challenges that modern scientists face, Boernsen *et al.* [64] recently reported on a controlled protein precipitation method combined with chip-based nano-ESI infusion mass spectrometry for profiling human plasma samples. It was reported that plasma is known as a very complex mixture with high albumin concentrations that make the analysis even more of a challenge. If one wishes to study the plasma metabolome, the sample pretreatment procedure should not affect this aspect of the sample. These researchers reported that when the plasma is slowly and carefully diluted in 50% organic solvent, slow protein precipitation occurs without small molecule loss. In Fig. 3.11a, a typical mass spectrum of infused fresh diluted plasma is shown. This sample is a representative of a typical "protein crash" where the proteins are rapidly denatured and the sample centrifuged to produce a biological supernatant sample for subsequent analysis. The multiple charged albumin peaks are very broad in such a sample, and almost no individual peaks are visible in this mass range as observed in Fig. 3.11a. Also, in the low mass range between m/z 100 and 900, the mass spectrum does not exhibit good spectral quality. In contrast, if one allows extended incubation times for a slow partial protein precipitation of the same sample, the resulting mass spectrum will change for the better. Figure 3.11b shows the same diluted plasma but after 16-h incubation time at 4°C. The total ion count has increased by a factor of 20. Also, in the low mass region between m/z 100

Figure 3.11 Typical mass spectrum after 10-min infusion of diluted human plasma (1:250) by 50% acetonitrile/water with 0.1% formic acid. (a) Fresh diluted plasma. (b) Typical mass spectrum under the same conditions but measured 16 h after dilution (method a). See text for experimental details. *Source:* Reprinted with permission from Boernsen KO, Gatzek S, Imbert G. Controlled protein precipitation in combination with chip-based nanospray infusion mass spectrometry. An approach for metabolomics profiling of plasma. *Anal Chem* 2005;77(22):7255–7264.

and 900, there is improved spectrum quality. The typical signal increase is shown again in the embedded figure where the x-marked peak has increased dramatically.

This example highlights a benefit of optimized sample pretreatment coupled with infusion chip-based nano-ESI mass spectrometry. In this approach, unwanted discrimination of sample components inherent in many sample extraction procedures as well as concomitant discrimination that sometimes occurs as part of the chromatographic process (changes in three-dimensional protein structure, etc.) are avoided. Thus, the infusion mass spectrum shown in Fig. 3.11b represents the composition of the entire sample, and this chip-based infusion approach offers the ability to easily measure hundreds of compounds in parallel with excellent reproducibility. Although ion suppression no doubt exists, it is reduced due to the benefits of nano-ESI [64].

3.4.4.5 Noncovalent Interactions. It has long been known that biospecific noncovalent interactions play a key role in life processes as well as the effectiveness of drug host–guest interactions. Important biological functions are also known to be mediated through noncovalent interactions between biopolymers and other components existing in the cell. Although certain spectroscopic techniques have been used to shed some

light on studies involving both qualitative and quantitative aspects of these noncovalent interactions, it was not until the early 1990s that electrospray mass spectrometry was shown to be a uniquely useful tool for studying these biomolecular structures and noncovalent interactions [65–75]. In some of these reported studies, the quantity of receptor and related chemicals was very limited and very costly. These experiments were typically done by infusing the sample via a syringe pump at 5–50 microliters/min when often only a small quantity of sample was available. In addition, often these experiments involved spraying totally aqueous solutions at neutral pH, which can be rather challenging under ordinary electrospray conditions where sometimes the limited sample was consumed before meaningful results were obtained. What was needed was an approach which provided very mild nano-ESI-MS conditions such that reliable results could be obtained while minimizing the quantity of sample consumed during the experiments.

A good example of a step forward in this approach was reported by Zhang *et al.* [55]. This report described using a chip-based nano-ESI system to perform a quantitative study for competitive binding noncovalent interactions between ribonuclease A (RNase A) and cytidylic acid ligands (2'-CMP, CTP), a well-characterized model protein–ligand complex, and between an inactive endocellulase mutant and four oligosaccharide ligands. Both titration and competitive binding approaches were performed before automated nano-ESI-MS analysis with a QTOF mass spectrometer. The latter provided a selective measurement of the actual noncovalent complexes and unbound species immediately following these traditional binding experiments. Dissociation constants for each complex were calculated from the sum of ion peak areas of free and complexed proteins during the titration and competition experiments. The measured K_d values for the RNase A–CMP and other complexes were found to be in excellent agreement with the available published values obtained by standard spectroscopic titration techniques. These experiments were performed in an automated manner and in replicates of three, thus providing a rigorous and thorough evaluation of the competitive binding results. In the wake of this report, a number of pharmaceutical researchers have employed this automated nano-ESI-MS approach to screen their combinatorial products or new chemical entities against selected protein targets.

3.4.4.6 Lipid Characterization. Lipidomics is defined as the large-scale study of the pathways and networks of cellular lipids in biological systems and has emerged to become an important new field of scientific endeavor. The study of lipids by mass spectrometry has increased markedly in the past 10 years. Both electrospray ionization [76] and more recently MALDI [77] coupled with mass spectrometry have been shown to provide very important analytical characterization capabilities for this complex class of biological molecules. Lipids in general span a wide range of polarities with many close similarities including isomers with important subtle unsaturation and other structural differences. Consequently, even modern chromatographic separation techniques including UPLC do not provide sufficient separation efficiency when combined with MS to adequately characterize these compounds. As a result, some researchers have explored the potential to simply infuse whole lipid extracts to a mass spectrometer using electrospray ionization. Although Murphy *et al.* were among the first to explore this route [76], there have been a number of other pioneers in lipid mass spectrometry studies to follow suite [14,76,78,79].

A nice example of the relative benefits of sample infusion of the entire sample extract containing lipids was reported by Han *et al.* [13]. These workers reported an increased differential ionization of multiple phospholipid classes through infusion microfluidics with chip-based ionization resulting in substantial enhancement of intrasource separation/selective ionization of phospholipid classes in comparison to the conventional ion source. Earlier, Han *et al.* [14] had demonstrated the differential ionization efficiency of lipid classes based on their inherent electrical properties, and they subsequently referred to this as “intrasource separation.” These researchers described these phenomena as benefiting from the achievement of a minimal flow rate of infusion to flow rates of <500 nL/min. This behavior was prescribed as benefiting from the efficient ionization provided by an optimized chip-based Taylor cone under very low flow, microfluidic nanospray conditions.

With reference to Fig. 3.12a and b, several fundamental observations were made. First, the infusion nanospray mass spectrum of a diluted solution of mouse myocardial lipid extract acquired in the negative ion mode showed abundant ions corresponding to anionic phospholipids. Thus, the intensities of m/z 678.5 and 834.5 observed in Fig. 3.12a with the conventional syringe-based infusion were substantially enhanced

Figure 3.12 Comparisons of ESI mass spectra of mouse myocardial lipids acquired from an ion source coupled to a syringe-pump-driven interface to that obtained using a nanomate nano-ESI interface. Mass spectrum in (a) was acquired in the negative ion mode directly from a diluted lipid extract infused with a syringe pump-driven interface. The mass spectrum in (b) was acquired in the negative ion mode directly from a diluted mouse myocardial lipid extract. See Text for experimental details. *Source:* Reprinted with permission from Han X, Yang K, Gross RW. Microfluidics-based electrospray ionization enhances the intrasource separation of lipid classes and extends identification of individual molecular species through multidimensional mass spectrometry: development of an automated high-throughput platform for shotgun lipidomics. *Rapid Commun Mass Spectrom* 2006;22:2115–2124.

in Fig. 3.12b which employed chip-based nano-ESI infusion. Second, the ionization efficiency of the ions corresponding to the doubly charged cardiolipin molecular species were also greatly increased in the microfluidic-based ionization system relative to those ionized in an ion spray source coupled with a typical syringe pump-driven interface. In addition, the peak intensity ratio of ions at m/z 693.5 and 686.5, corresponding to 15:0–15:0 phosphatidylglycerol (PtdGro) and 16:1–16:1 phosphatidylethanolamine (PtdEtn), respectively, was approximately three times higher in the mass spectrum acquired via the chip-based microfluidic approach in comparison to that acquired with the syringe pump-driven capillary device. Finally, interfering ions corresponding to chlorine adducts of some components (e.g., those at m/z 708.5 and 850.5) were in very low abundance in the mass spectra acquired using the microfluidic approach thereby resulting in a much clearer spectrum for anionic phospholipid characterization (Fig. 3.12b) [14]. These results corroborate the contention that microfluidics applied to nanospray mass spectrometry facilitates the intrasource separation/selective ionization of lipid classes and particularly improves ionization with doubly charged molecular species (e.g., cardiolipin in this case).

3.4.4.7 Carbohydrates. The comprehensive characterization of a complex carbohydrate sample is a challenging endeavor. Although comprising but a small number of different monomers (hexose, *N*-acetylhexosamine, deoxyhexose, etc.), the variable positions of linkage, coupled with branching; the stereochemistry of monomers; and linkage anomericity quickly inflate to a huge number for even a small set of residues. With the added complication of branching, a neutral MS loss may originate from multiple antennae, and as is common, analytes in low abundance can be obscured by more prominent ions.

A comprehensive carbohydrate sequence is particularly challenging when considering the constitutional and stereoisomers that are abundant in glycan arrays. Not only are these compounds somewhat challenging to ionize via electrospray but also they are structurally very similar and complex with many closely related isomers. Constitutional isomers, also referred to as *structural isomers*, are defined as an identical atomic composition arranged in a different structure. Stereoisomers are exemplified with those frequently encountered in the hexoses, mannose, galactose, and glucose.

In a recent report [80], Reinhold *et al.* demonstrated the use of sequential mass spectrometry (MS^n) to define previously unreported structural isomers and qualitative aspects in complex mixtures without prior chromatographic separation. Although the analytical potential of various on-line chromatographic approaches is acknowledged, they emphasize the benefits of continuous infusion for providing the needed time for MS^n experiments as well as the merits of signal averaging when the increasingly weak MS^n ion current signal is observed. The principles involved have been previously considered [81], and complex biological applications recently reported [82]. The overall focus has been to better define MS^n as a universal sequencing strategy consistent with the goals of automation and high-throughput analysis.

In Reinhold's report, mass spectra were obtained from a LIT equipped with a nano-ESI ion source [80]. The mass spectra were collected automatically using the software of the combined systems. Ten scan events were programmed with the first event, scan event 1, being a profile analysis. Subsequent ion scans were automatically selected as the most abundant or from a preprogrammed neutral loss list. In situations where more than one product mass satisfied the neutral loss list, the more intense product was

selected as the precursor for a subsequent scan. Signal averaging was accomplished by increasing the number of microscans for each scan and was generally between 5 and 50. This improved spectral quality was necessary at the higher orders of MS^n due to diminishing ion current signal, particularly beyond MS^5 or MS^6 .

This analytical approach was demonstrated using a sample previously identified to contain a variety of structural isomers. In ovalbumin, several structural isomers have been reported with the composition $Man_3GlcNac_5$ and observed as the methylated, reduced ion at m/z 1923. Sequential fragmentation of this precursor, m/z 1923.1–1663.8, 130.6, 111.5, and 852.4, provided the subsequent spectra, MS^2 – MS^6 . The most abundant ions in the spectra (MS^{2-4}) result from a facile loss of nonreducing terminal HexNacs or the reducing-end GlcNAcol. In the MS^5 spectrum, a fragment ion m/z 893.5 was consistent with loss of a terminal hexose (i.e., fully methylated at all nonanomeric positions). These authors conclude that a distinct pattern of fragments could be discerned for each isomer thus providing a unique and viable approach for glycan structure elucidation [80]. It was also concluded that the extended analysis time and minimum sample consumption of nano-ESI-based infusion of these samples is the key for providing the quality and level of mass spectral described in these studies.

3.5 QUALITATIVE ANALYSIS

Mass spectrometry has long been recognized as a very useful analytical tool for the qualitative determination of compound structures. Coupled with NMR techniques, complete structural characterization including stereochemistry can often be accomplished for previously unknown structures ranging from natural products to biopolymers. However, even modern micro-NMR techniques do not possess the very high sensitivity that may be routinely accomplished by mass spectrometry. Therefore, the latter is the primary technique for structural elucidation of unknown compounds.

Although LC/MS/MS and related techniques are possible with a separation science technique coupled with mass spectrometry, often the high quality, full-scan mass spectral data often required for structural elucidation is not possible in the “on-line” mode (see above). This is because of the need for a relatively slow scan rate of the mass spectrometer to acquire these data, which is not easy to accomplish while a chromatographic peak elutes within a few seconds. In most instances, the highest quality mass spectral data are obtained by collecting an HPLC or UPLC peak followed by the continuous infusion of this now “clean” sample to the mass spectrometer. This experiment provides much more time to acquire the full-scan mass spectral data with concomitant signal averaging for an improved signal-to-noise ratio as well as allowing for a sequence of MS/MS experiments to be performed which are readily available from modern MS systems. Most modern LC/MS/MS systems do not provide sufficient time during the chromatographic peak elution to perform multiple full-scan MS/MS experiments. This is especially true for FT-ICR and ion mobility systems [83,84].

Several examples for the qualitative characterization of chemical compounds by infusion nano-ESI have been discussed above. In an earlier drug metabolism study, sequential on-line fraction collection of an entire chromatographic run over short time segments followed by robotic infusion of selected fractions which correspond to chromatographic peaks of interest was discussed [56]. A very different approach is to use the infusion of a host–guest complex to study the qualitative aspects of biospecific

noncovalent complex interactions [66]. An alternative elegant approach is described above in Section 3.4.4.7 where sequential MSⁿ experiments are performed on complex glycans, which can provide unique qualitative insight into the detailed structure of these challenging yet biologically important compounds [80].

3.6 QUANTITATIVE ANALYSIS

3.6.1 Small Molecule GLP Bioanalysis

Historically, over the past 20 years, the quantitative determination of drugs and their metabolites has been developed, matured, and accepted using HPLC coupled with tandem mass spectrometry (MS/MS) [85]. In the vast majority of cases, triple quadrupole mass spectrometers have been shown to be the preferred MS/MS tool for performing these experiments. Although ion trap [86] and TOF [87] mass spectrometers have been shown capable of providing quantitative LC/MS results, the triple quadrupole system has become the accepted gold standard within the pharmaceutical industry as well as in many other applications demanding high quality quantitative results. The benefits of LC/MS/MS include a final “separation” of chemical and matrix components before MS analysis, concentration of the analytes of interest in the HPLC (or UPLC) peak for improved sensitivity, a reduction in matrix suppression of ionization as a result of the chromatographic separation, and a retention time for the targeted components as an additional element of selectivity. In addition, at least two modes of ionization, electrospray and APCI, are available to handle the wide diversity of chemical compound classes. In contrast, the time needed for adequate chromatography leads to a reduction in sample throughput when large batches of samples must be analyzed. As a result, there is growing interest in sample analysis with little or no on-line chromatography [88,89]. One of these approaches is flow injection analysis (FIA), which has been used quite successfully for carnitine biomarkers in newborn screening [90], while another is infusion of a suitably cleaned up sample [88]. In each of these approaches, there is no concentration of analyte from the extract as in a chromatographic peak or presence of a chromatographic peak retention time. However, there have been some reports of successfully performing quantitative analyses with an appropriate degree of prior sample preparation followed by rapid, sequential infusion of the sample extract containing a suitable internal standard.

Corkery *et al.* [91] reported on a chip-based quantitative method for the determination of gemcitabine. To focus on one aspect of this report, the authors described the combination of a novel particle discriminator interface (PDI) coupled with the ESI Chip (Advion BioSystems, Ithaca, NY) for the rapid (15 s), sequential, automated infusion of solid-phase extraction (SPE) extracts of biological samples following rigorous GLP workflow and guidelines for gemcitabine in human plasma. Specifically, a plasma calibration curve ranging from 0.5 to 250 ng/mL was prepared in duplicate with quality control (QC) samples analyzed in replicates of six at a low, mid, and high level of 0.5, 125, and 250 ng/mL, respectively. The isotopically labeled internal standard was fortified in each sample at 6 ng/mL. The linear calibration curve was calculated for regression analysis and gave an $R^2 > 0.998$. The accuracy and precision of the method was <20% for the lower limit of quantitation (LLOQ) and less than 15% for all other data points on the calibration curve. In general, all the usual GLP acceptance criteria were met with this infusion MS/MS method of analysis.

The authors summarize that the chip-based format coupled with the particle discriminator interface API inlet was sufficiently accurate, precise, and reproducible to meet standard GLP validation acceptance criteria. They concluded that this approach demonstrated a three times lower LLOQ than LC/APCI/MS/MS and that the analysis time and sample consumption of the former technique was reduced in comparison with the latter. With respect to matrix suppression of ionization in the absence of on-line HPLC, the authors report a matrix effect of 51% or a factor of 2 suppression. However, even though suppression was observed, the analyte and internal standard were suppressed to a similar extent, and there was no change in the variance of the blank (background), leading to little change in the LLOQ [91].

3.7 LIQUID EXTRACTION SURFACE ANALYSIS (LESA)

3.7.1 Profiling Thin Tissue Slices for Drugs and Their Metabolites

A modern trend in mass spectrometry is ambient ionization, which has demonstrated that direct surface sampling and mass spectrometric analysis without sample preparation is possible in many instances. Among the early entries to this field were direct analysis in real-time (DART), desorption electrospray ionization (DESI), extractive electrospray ionization (EESI), secondary electrospray ionization (SESI), and many combinations of desorption with postionization methods working at atmospheric pressure [92]. Two key components of these approaches are surface analysis without sample preparation with a common theme of forming ions at ambient pressure and temperature.

A recent twist to this approach has been reported by Kertesz and Van Berkel [93], which involves fully automated microliquid extraction-based surface sampling and ionization using a chip-based robotic nanoelectrospray system. In one sense, these reports are related to the other forms of surface sampling and ambient ionization, but in this latter instance, the difference is that analytes undergo a short, robotic microextraction process using a suitable extraction/spray solvent contained in a pipette tip followed by immediate nano-ESI infusion of the sample. This process is an extension of an earlier report which describes the direct ion spray MS analysis of samples from card-based SPE material [94].

This technique has been described as liquid extraction surface analysis with an acronym of LESA. This concept was first described by Kertesz and Van Berkel [93], where they adapted the above-described TriVersa NanoMate to form a microliquid droplet of extraction/nano-ESI spray solvent between the sample surface and the pipette tip typically used with this device (Fig. 3.13). In general, a new pipette picks up a solvent aliquot from the solvent reservoir (Fig. 3.13a) and then moves to place the pipette tip within close proximity to the sample surface to be analyzed (Fig. 3.13b). The microdroplet accomplishes a microextraction of chemical constituents present on or within the sample surface and then transfers this extracted sample directly to the ESI Chip described above for automated infusion nano-ESI-MS analysis of the extract (Fig. 3.13c). Extraction of soluble analytes occurs at the interface between the microliquid droplet and the sample. The resulting extract solution is withdrawn into the pipette and delivered directly to the ESI Chip for infusion nano-ESI-MS or MS/MS analysis of the extract mixture.

Figure 3.14a–d shows an example where a tissue from a mouse dosed with sulforaphane was examined using the LESA technique. The SRM ion current signal levels

Figure 3.13 (a–c) Schematic representation of liquid extraction surface analysis (LESA). (a) Pipette tip aliquots from a solvent reservoir. (b). Close-up photo of the microdroplet liquid junction between the pipette tip and the surface to be extracted. (c) Depiction of pipette tip delivering the microextract from the sample surface to the inlet of the ESI Chip for nano-ESI infusion MS or MS/MS analysis. *Source*: Reprinted with permission from Advion BioSciences, Inc., Ithaca, NY.

for (b) sulforaphane (m/z 178 $\rightarrow$ 114) (c) the GSH conjugate (m/z 485 $\rightarrow$ 308) and (d) the NAC conjugate (m/z 341 $\rightarrow$ 178) were recorded during 1-min spraying of samples taken at each point. Dwell time was 50 ms for each transition monitored. The extraction solvent was 80/20/0.1 (v/v/v) ACN/water/FA while the aspirated and dispensed solvent volumes were 3 and 2 μ L, respectively, and aspirated sample volume was 2 μ L. The areas sampled by LESA are annotated in the photograph of the tissue shown in Fig. 3.14a. The SRM “infusagrams” obtained for sulforaphane and its glutathione (SFN-GSH) and *N*-acetylcysteine (SFN-NAC) metabolites from the sequential sampling of the different organs are shown in Fig. 3.14b–d, respectively. The two compounds were not detected in the kidney or liver tissues (spots 2 and 5, respectively). On the other hand, NAC conjugate of sulforaphane was readily detected in the liver and kidney (spots 2 and 5, respectively), and only background level signals were recorded for the stomach and stomach walls (spots 1, 3, and 4, respectively) [95].

3.8 SAMPLING AND NANO-ESI MS/MS OF LIVE SINGLE CELLS

A final example of what may offer insight into future possibilities of infusion nano-ESI mass spectrometry is a report on live single-cell video mass spectrometry for cellular and subcellular molecular detection and cell classification [96]. These authors describe employing a modern pulled-capillary nano-ESI sprayer, which is used first as a sampling device for the cell contents followed by its use as a nano-ESI spray emitter. In general, a 2–10 μ m i.d. pulled-capillary is carefully inserted through the cell wall of a single live cell while observing the process under a suitable microscope. A small

Figure 3.14 (a–d) LESA tissue example. (a) Photograph of a sulfuraphane-dosed mouse. Sampling locations: 1 = stomach/contents; 2 = liver; 3 and 4 = wall of stomach; and 5 = kidney. SRM ion current signal levels for (b) sulfuraphane (m/z 178 $\rightarrow$ 114) (c) the GSH conjugate (m/z 485 $\rightarrow$ 308) and (d) the NAC conjugate (m/z 341 $\rightarrow$ 178) were recorded during 1-min spraying of samples taken at each point. *Source:* Reprinted with permission from Kertesz V, Van Berkel GJ. Fully automated liquid extraction-based surface sampling and ionization using a chip-based robotic nanoelectrospray platform. *J Mass Spectrom* 2010;45:252–260.

portion (one picoliter) of the cell contents is aspirated into the tapered pulled-capillary sampling device and withdrawn from the cell medium. A 1 μ L portion of appropriate aqueous organic spray solvent is manually introduced through the opposite, larger opening of the pulled capillary via syringe while avoiding the formation of an air bubble gap between the introduced solvent and the cell contents. The pulled-capillary spray emitter is then placed at the inlet position of an API tandem mass spectrometer, and the nano-ESI high voltage turned on to commence static nano-ESI analysis of the cellular contents.

Figure 3.15a–g shows a representative set of nano-ESI-MS/MS data for a series of experiments, which sampled cellular cytoplasm, granules, and extracellular contents from a single live cell. These data show molecular identification of cell-specific peaks by MS/MS analysis. Cytoplasm (a) or a granule (b) in a single cell was microsucked into nanospray tips. The positive ion mass spectra of the cytoplasm (a) and a granule

Figure 3.15 (a–g) Molecular identification of cell-specific peaks by MS/MS analysis. See text for experimental description and details. *Source*: Reprinted with permission from Mizuno H, *et al.* Live single-cell video mass spectrometry for cellular and subcellular molecular detection and cell classification. *J Mass Spectrom* 2008;43:1692–1700.

(b) of a cell were superimposed to show the overall difference (d). The site-specific peaks were analyzed by MS/MS, while granule-specific peaks at m/z 112 (e) and m/z 335 (negative ion) (g) were identified as due to histamine and leukotriene B4, respectively. The nonsite-specific molecular ion peak at m/z 177 was identified as that of serotonin (f). The mass spectrum inset (in c) was a positive ion mass spectrum of the medium sucked from a point near a reacting cell after stimulation. The released histamine from RBL-2H3 granules was detected at m/z 112.

3.9 CONCLUSIONS

In summary, LC/MS and LC/MS/MS techniques are here to stay and will continue to be applied to many important applications in the future. One of its key benefits is the “compression” or concentration of the entire analyte into a chromatographic peak which can provide good sensitivity. Continuous nano-ESI infusion does not provide this concentration effect, but it does allow for signal averaging and improved sensitivity due to the formation of very small droplets in the electrospray aerosol which can help improve sensitivity. In many instances, LC/MS run times are so short (1–2 min) that minimal chromatography is occurring, and many of the HPLC peaks are complex mixtures themselves. In these and certain other instances, a judicious choice and application of little or no sample preparation coupled with nano-ESI infusion of the

cleaned up extract can often provide the qualitative and sometimes the quantitative data quality required. In these latter applications, all the issues associated with operating and maintaining an HPLC system are replaced by a simple, cheaper, faster, and automated infusion nano-ESI experiment. As with any choice of techniques for solving a problem, a careful decision for the appropriate tools and techniques employed should be considered to best solve the problem at hand and hence obtain the optimal data quality required.

4.1 SUMMARY

Since the introduction of matrix-assisted laser desorption ionization (MALDI) and electrospray ionization (ESI) in the 1980s and the continued advancements in instrumentation, mass spectrometry (MS) has become the premiere method for scientific analyses because of its high sensitivity and molecular specificity. ESI and MALDI have played key roles in the development of MS for biological applications. However, in order to continue to expand the number of applications that can be addressed using MS, recent research has focused heavily on the development of several novel “ambient” ionization techniques.

Development of ambient ionization techniques is arguably one of the fastest growing fields in MS. Interest exists in the ability to conduct ionization in the open air with no vacuum constraints, thus increasing the number of applications amenable to MS. In addition, these techniques allow for faster analysis times because of limited sample preparation. A plethora of ambient ionization techniques, along with their associated abbreviations, have been introduced in the past decade. To provide a perspective to the reader, this chapter provides a brief review of ionization in MS; however, the focus is

on techniques introduced over the last several years. These techniques are divided into three main categories:

1. Spray-based ambient ionization techniques
 - a. Desorption electrospray ionization (DESI)
 - b. Desorption sonic spray ionization (DeSSI) or easy ambient spray ionization (EASI)
 - c. Desorption atmospheric pressure photoionization (DAPPI)
2. Electrical discharge ambient ionization techniques
 - a. Direct analysis in real time (DART)
 - b. Atmospheric pressure solids analysis probe (ASAP)
 - c. Desorption atmospheric pressure chemical ionization (DAPCI)
 - d. Dielectric barrier discharge ionization (DBDI)
 - e. Plasma-assisted desorption ionization (PADI)
3. Laser-assisted desorption electrospray ionization techniques
 - a. Electrospray-assisted laser desorption ionization (ELDI)
 - b. Matrix-assisted laser desorption electrospray ionization (MALDESI)
 - c. Laser ablation electrospray ionization (LAESI) and infrared laser-assisted desorption electrospray ionization (IR-LADESI)

The specific techniques listed (see above) were chosen on the basis of their varying ionization mechanisms and currently are the more reported methods in the literature. Each technique is described in detail utilizing accompanying schematics. In addition, other ambient techniques that are similar to the ones above, in regard to mechanisms and setups, are briefly described where appropriate. Little emphasis is placed on the exact mechanism of each technique, since most are still under investigation; however, relevant references are provided to direct the interested reader. Reported studies involving applications encompassing both small (e.g., metabolites) and large (e.g., peptides and proteins) molecules are summarized where possible for each technique.

The conclusion section comments on the current state of ambient ionization and discusses future advances that are warranted before the realization of the full capabilities of these methods.

4.2 INTRODUCTION—IONIZATION IN MASS SPECTROMETRY

While the art, science, and practice of MS is over a century old, significant advances in technology have allowed it to more effectively address contemporary questions related to human health and disease, national security, environmental issues, and drug discovery, among many others. Since ionization is essential for mass spectral analysis (i.e., neutrals are not detected) and this chapter is centered on the development of novel ambient ionization methods, it is instructive to briefly discuss the history of ionization methods in MS.

Seminal work by A. J. Dempster led to the development of the first mass spectrometer and the electron impact ionization (EI) method around 1920 [1]. In EI, molecules

are bombarded with high energy electrons (~ 70 eV) leading to ejection of an electron from the analyte and ionization. While EI has undergone significant improvements, nearly 100 years later it remains a major workhorse for MS. Introduced several decades later in the 1950s, chemical ionization (CI) was reported by Munson and Field [2,3]. This technique makes use of ion–molecule reactions and allows for the measurement of intact molecular ions as opposed to EI, where the molecular ion tends to undergo extensive fragmentation. In 1969, Beckey introduced field desorption (FD) for the analysis of organic molecules [4,5]. MacFarlane and Torgerson later presented plasma desorption (PD) [6] in 1974, which, for the first time, allowed ionization of large, polar, and nonvolatile biological molecules. Nearly a decade later, Barber *et al.* introduced fast atom bombardment (FAB) [7], which largely shadowed PD as it did not require a time-of-flight (TOF) mass analyzer and was not a radioactive ionization source. In 1984, Fenn and coworkers demonstrated ESI [8] for the analysis of macromolecules by imparting multiple charges on the analyte. In 1987, through independent efforts, Tanaka [9] and Karas and Hillenkamp [10,11] introduced MALDI, which generates singly charged ions of large biopolymers. It is important to note that ionization methods such as EI, CI, FD, and FAB are still in use today although ESI and MALDI have revolutionized MS. This is recognized in part by the awarding of the Nobel Prize in 2002 to Fenn and Tanaka for their inventions [12].

In summary, the rate of introduction of new ionization sources to MS spanning a period of almost 70 years (EI—1918 to MALDI—*ca.* 1987) is ~ 0.15 sources/year. This includes other ionization sources not specifically mentioned above such as thermospray (TS) [13], secondary ion mass spectrometry (SIMS) [14,15], inductively coupled plasma (ICP), [16] and its predecessors for elemental analysis: thermal ionization [17] and spark source [18]. This modest introduction rate of new ionization sources is interesting and quite surprising because ionization of a neutral molecule is a prerequisite for subsequent mass analysis. In the past decade, there has been significant acceleration in the development of ionization technology as over 25 ambient techniques have been introduced [19].

4.2.1 Ambient Ionization Techniques

A general definition of an ambient ionization technique is any method that can directly analyze species either deposited or naturally occurring on a surface (e.g., metabolites in a leaf) at atmospheric pressure with limited to no sample preparation. These methods differ from ESI, which is performed at atmospheric pressure but is not capable of direct analysis since significant sample preparation is required. These techniques are also different from MALDI and SIMS, which are capable of direct analysis of surfaces; however, they are performed *in vacuo*. These capabilities significantly reduce analysis times for two main reasons: (i) no lengthy sample extraction, preparation, and chromatography is required as material can be analyzed directly from the surface and (ii) no time-consuming vacuum pump downs as analysis occurs in open air. In addition, performing ionization outside the instrument expands the breadth and geometry of samples amenable to MS detection. This ultimately opens new avenues of research that only a short time ago would not have been applicable to MS.

The purpose of this chapter is not to provide an exhaustive review of every technique and its applications; this would be quite complex and may require a whole book unto itself, but rather to provide an overview to the reader on this new, exciting,

and promising arena in MS. As recently described by Fernandez and coworkers [20], the techniques discussed in this chapter are organized into three subgroups based on their mechanisms and include (i) spray-based techniques, (ii) electrical discharge techniques, and (iii) laser assisted desorption electrospray ionization techniques. Setups and mechanisms are briefly discussed while commenting on relevant applications. The chapter concludes with a detailed discussion on some of the widely reported applications and current limitations. Techniques introduced in the past decade but not explicitly mentioned in this chapter include laser-induced acoustic desorption ionization (LIAD) [21,22], radio acoustic desorption and ionization (RADIO) [23], infrared laser ablation metastable-induced chemical ionization (IR-LAMICI) [24], and atmosphere pressure glow discharge (APGD) [25,26]. For the interested reader and to supplement the information described herein, several reviews have recently been written on ambient ionization [19,20,27].

4.3 SPRAY-BASED IONIZATION TECHNIQUES (DESI, DESSI, DAPPI)

Reported by Takats *et al.* in 2004 [28], desorption electrospray ionization (DESI) arguably initiated the “gold rush” in the development of novel ionization methods. The report was significant for two main reasons: (i) demonstration of direct mass spectral analysis of species from a variety of surfaces (e.g., conducting, insulating, *in vivo*) and (ii) this was the first method aside from ESI that could produce multiply charged species from high molecular weight analytes. In general, multiple charging of species is advantageous for several reasons, including (i) increases in the detectable mass range, (ii) multiply charged species are more conducive to typical dissociation methods [e.g., collision-induced dissociation (CID), electron capture dissociation (ECD), and electron transfer dissociation (ETD)], (iii) and offers several advantages for FTMS-based instruments (e.g., increased resolving power and mass accuracy).

The DESI source essentially consists of a three-way tee in which nitrogen is supplied to one port while the liquid is infused through a silica capillary. The liquid is charged through application of a high voltage via a liquid junction. The pneumatically assisted charged mist is directed at an analyte-bearing surface where species are desorbed and transferred to the atmospheric interface of the mass spectrometer. Figure 4.1 displays a typical schematic of the DESI process and introduces several geometric parameters whose optimizations are essential for sensitive DESI-MS analysis [29]. Typical values for these parameters include $\sim 50^\circ$ for α (angle of incidence), $0\text{--}10^\circ$ for β (angle of collection), $2\text{--}3\text{ mm}$ for d_1 (distance between emitter tip and surface), and $0\text{--}1\text{ mm}$ for d_2 (distance between MS capillary and surface). It is important to stress that these values are representative of literature reports, and further exploration may be warranted to achieve optimal sensitivity and depend on several factors related to specific experiments (e.g., solvent flow rate, nebulizer gas velocity, and surface characteristics).

Early reports emphasized at least two different mechanisms of ionization in DESI [28–30], depending on the analyte and geometric parameters utilized; however, further research seems to have come to a consensus on a two-step process referred to as the *droplet pick-up mechanism* for desorption and ionization. Species are first dissolved by a thin liquid film created via the accumulation of solvent on the surface. Next, small analyte-containing secondary droplets are desorbed from the thin solvent film on the surface via a combination of incoming charged droplets and nitrogen

Figure 4.1 The DESI source consists of two concentric capillaries in which nitrogen gas is supplied to the outside capillary and solvent is infused in the inner capillary. The charged pneumatically assisted spray is directed at an analyte-bearing surface where material is solubilized and secondary analyte-containing droplets are sampled by the atmospheric interface of the mass spectrometer. Optimizing the geometry of the source is critical in achieving high signal intensity. See text for a full description of geometric parameters. (See color insert.)

gas. After liberation from the surface, secondary analyte-containing droplets are transferred to the atmospheric interface of the mass spectrometer via a combination of factors including the dynamic drag of the vacuum interface, coulombic repulsion, and flow of nitrogen gas reflecting off the surface. Ionization is analogous to ESI following well-established charge residue [31,32] or FD theories [33,34]. Reports utilizing orthogonal measurement methods [35–37], computational fluid dynamic modeling [38,39], and thermometer ions [40] have contributed to the development of the current droplet-pickup theory and the interested reader is directed to these reports for further information. DESI has been utilized to analyze a range of species from small molecules (e.g., lipids [41,42], amino acids [43], explosives [44–47], carbohydrates [48], nucleobases [49], metabolites [50–54], pharmaceuticals [55–57] to industrial polymers [58,59] and intact proteins [60–63] from both conducting and insulating surfaces. The technique has been coupled to most mass spectrometers, including Fourier transform ion cyclotron resonance (FT-ICR) [48,60,64], orbitrap [65], two-dimensional ion trap [28], triple quadrupole [66,67] and other hybrid MS platforms [55,68,69].

While significantly understudied, the type of surface plays a major role in DESI. For samples in aqueous solutions, the deposition of these samples onto a hydrophobic surface forms a smaller diameter spot than a corresponding hydrophilic surface (e.g., plain glass) [70]. Consequently, samples are more concentrated (material per unit area) when using a hydrophobic surface leading to more material desorbed by DESI and higher signal intensity. However, not all analytes give an adequate signal from hydrophobic surfaces. For example, carbohydrates, intrinsically very hydrophilic, have little interaction with hydrophobic surfaces (e.g., polytetrafluoroethylene (PTFE)) and as a consequence of turning on the high pressure gas are completely removed from the surface [48]. For carbohydrates, more hydrophilic surfaces are warranted. For method development in DESI, it is advantageous to survey several types of surfaces with varying characteristics (e.g., roughness, hydrophobicity, and conductivity) before beginning experiments.

Figure 4.2 A schematic of transmission mode DESI. A variant of conventional DESI, sample (S) is deposited onto a mesh screen, which is then placed on-axis in between the ESI emitter and inlet of the mass spectrometer. D_{TC} is the distance from electrospray tip to capillary and D_{SC} is distance from sample to capillary. *Source:* Used with permission from Ref. 72.

In its most common form, the DESI source resembles the schematic in Fig. 4.1; however, variants of this design have been recently introduced to minimize the effects of geometry (see above) on signal intensity. As a result, these new configurations have effectively increased the robustness and therefore the reproducibility of DESI. Cooks and coworkers have performed DESI in a small pressure-tight stainless steel enclosure where the spray and MS capillary are parallel to each other [71]. They report a reduced dependence of geometry on signal intensity and similar sensitivities when compared to conventional DESI. In addition, the enclosed DESI source protects the analyst from exposure to organic solvents or other toxic/infectious materials that may be under investigation. In another variation, termed *transmission mode desorption electrospray ionization* (TM-DESI), Brodbelt and coworkers described the application of analyte onto a mesh screen, which is then placed between the ESI emitter and MS capillary [72]. This in-line arrangement of components (Fig. 4.2) significantly reduces the geometric degrees of freedom and according to these authors leads to more efficient optimization; however, this technique is less suited for bulk materials and *in vivo* analyses. More recent studies, using TM-DESI, have investigated the importance of surface and mesh characteristics on analyte desorption [73] and have shown increased selectivity using a mesh-bound photocleavable agent to selectively capture thiol-containing compounds from a mixture [74]. The continued refinement of DESI will aid in achieving the most robust configuration.

By merely turning off the voltage of a typical DESI setup and increasing the gas velocity, one can perform desorption sonic spray ionization prior (DeSSI) [75]. DeSSI, synonymously referred to as *easy ambient sonic spray ionization* (EASI) [76–78], is a hybrid technique taking characteristics from both DESI [28] and from sonic spray ionization [79]. Since no potential bias is applied, the spray plume in DeSSI is essentially neutral and the charging of molecules is a result of the statistical fluctuations of the distribution of cations and anions within the solvent droplets. Reports indicate similar sensitivities for small molecules when compared to DESI (with high voltage) for the analysis of drug tablets [75]. This technique may be well suited for small molecule analyses because of the absence of solvent clusters in the low m/z range that occur when performing conventional DESI. In addition, DeSSI could be well suited for field

Figure 4.3 A schematic of the DAPPI source. The interaction of heated solvent molecules and photons leads to desorption and ionization of analyte. Ionization is based off APPI mechanisms and as a result the choice of dopants (solvents) is critical for achieving optimal ionization. *Source:* Used with permission from Ref. 89.

analyses (e.g., pesticides, herbicides, and explosives) using portable mass spectrometers [80–88], where access to a high voltage power supply is less practical.

Instead of a jet of charged liquid droplets, DAPPI employs a jet of heated gas solvent molecules (e.g., toluene) and photons as the driving forces for analyte desorption and ionization [89]. A schematic of the setup is shown in Fig. 4.3, where a solvent jet is created at an angle of 45° to the surface by a microchip nebulizer and photons are emitted from a krypton lamp (10 eV) perpendicular to the plane of the surface. Since desorption of analyte is attributed to thermal processes, DAPPI is mainly limited to smaller molecules that are semivolatile. Ionization is analogous to atmospheric pressure photoionization (APPI) [90] and, as a result, the choice of dopants (i.e., solvents) plays a critical role in the type of ionic species observed. Preliminary data show promise for the analysis of metabolites and pharmaceuticals with limits-of-detection (LODs) ranging from 56–670 fmol for selected analytes. A clear advantage exists for the analysis of neutral and less polar species by DAPPI over the more widely reported DESI technique [89].

4.4 ELECTRICAL DISCHARGE IONIZATION TECHNIQUES (DART, ASAP, DAPCI, PADI, DBDI)

DART is currently one of the most reported ambient ionization techniques in the literature and was introduced shortly after the first report of DESI by Robert Cody *et al.* in 2005 [91]. A schematic of a basic DART source is shown in Fig. 4.4 and mainly consists of a tube divided into three different chambers in which a gas, typically helium or nitrogen, flows at $\sim 1\text{--}5\text{ L/min}$ [91]. Ions and metastable atoms or molecules

Figure 4.4 A schematic of the DART source. Plasma is generated as a result of an electrical discharge. Ions are then separated from the plasma and the metastable gas molecules are directed at the surface.

(depending on the gas used) are created through an electrical discharge via application of a high voltage (3–5 kV) between the needle electrode and grounded counter electrode [92]. Ions are then removed from the plasma through a second region that is electrically biased and the gas is subsequently heated in the third compartment before exiting the source. The stream of excited gas molecules is then directed toward an analyte-bearing surface located on or off axis between the source and atmospheric interface of the mass spectrometer.

The driving force for desorption is reportedly a result of thermal processes that limit the technique to relatively low molecular weight semivolatile species [27]. The ionization mechanism(s) of DART involves the production of protonated water clusters via Penning ionization of excited He molecules (2^3S 19.8 eV) [91]. These gas-phase reagent ions quickly react with the desorbed analyte molecules to predominantly produce protonated species via proton transfer. This proton transfer mechanism is dependent on analyte molecules having higher proton affinities than the ionized water clusters [92]. Other ionization pathways are possible and are often analyte dependent [92,93].

Although the ionization and desorption processes in DART are still under investigation [92,94,95], the technique has been used to analyze a diverse set of analytes from various surface types. These applications include the analysis of self-assembled monolayers on gold surfaces [93], analysis of fatty acids from bacterial cells [96], analysis of counterfeit drugs [97], species separated on planar chromatographic plates [98], melamine detection in contaminated pet food [99], metabolomic fingerprinting [100], the determination of acrylamide in drinking water [101], and the analysis of alkaloids from plant tissue cultures [102,103]. In recent research, Fernandez and coworkers reported desorption electrospray metastable-induced ionization (DEMI) [104], a hybrid of DART and DESI. This technique is aimed at circumventing the limitations of ionization in DESI (i.e., nonpolar molecules) and DART (i.e., molecular weight limited).

Another electrical discharge technique, termed *atmospheric pressure solids analysis probe*, uses a heated nitrogen gas stream (100–500°C) to desorb semivolatile species existing in liquid or solid form from a melting point capillary that is placed into the source region, as shown in Fig. 4.5. Spearheaded by Larsen and coworkers, the main advantage of ASAP is that the method is easily implemented, requiring only minor modifications, on existing or commercial ESI/APCI (atmospheric pressure chemical ionization) sources [105]. This simplicity reduces the cost associated with machining or purchasing a commercial source. Following thermal desorption via the heated gas, gas-phase analyte ions are then ionized via a corona discharge within the source and

Figure 4.5 A cross-sectional view of an ESI/APCI source modified for ASAP analysis. *Source:* Used with permission from Ref. 105.

sampled by the atmospheric inlet of the mass spectrometer. Mechanisms of ionization are similar to traditional discharge APCI techniques. While DART and ASAP both utilize heated gas jets and electrical discharges for desorption and ionization, respectively, ASAP does not selectively remove ions from the plasma as in DART. However, both DART and ASAP have been found to produce similar spectra in negative ion mode, suggesting similar modes of ionization [95].

Besides the ease of implementing the ASAP technique, another noteworthy advantage is that desorption and ionization are performed in an enclosed area from where the waste can be vented, thereby preventing exposure to potential toxic materials that may be under interrogation [105]. The versatility and rapid analysis of the technique was presented in the original publication, where mass spectral analysis of plant tissues, plastics, and paper currencies were obtained in <10 s [105]. More recently, ASAP has been used for the determination of the effects of various inhibitors on the ergosterol pathway in fungal cells [106].

Developed by Cooks and coworkers, DAPCI was first used to investigate the potential mechanisms of DESI [29,107]. The technique, a surface sampling variation of APCI and mechanistically similar to both DART and ASAP, uses a tapered stainless steel needle in place of the ESI emitter in DESI. As a result, the setup of the DAPCI source is quite similar to DESI with minor geometric differences. Vapors of various solvents (e.g., toluene, acetone, and methanol) are mixed into the annular nitrogen gas

flow via a T-junction while a voltage of 3–6 kV is applied to the stainless steel needle, which then initiates a corona discharge. Gaseous ions and molecules desorb species from the surface, and ionization occurs through charge transfer and gas-phase ionization. DAPCI has shown advantages over DESI for ionization of less polar analytes [29]. DAPCI has been used for the nonproximate analysis of various small molecule species [108], detection of melamine in milk [109], and analysis of various explosives [107].

The last two techniques in this group of electrical discharge ionization methods are DBDI [110] and PADI [111]. Both are relatively new to the field and limited reports on exact mechanisms and applications currently exist. These two specific techniques differ from DART, ASAP, and DAPCI in that they utilize an alternating voltage to create a low temperature discharge to drive desorption and ionization as opposed to a high voltage electrical discharge. DBDI utilizes a dielectric material placed between a needle and a counter electrode in which an alternating voltage is applied (3500 V), creating a dielectric barrier discharge [112]. The dielectric material limits the amount of current between the electrodes and as a result a stable low temperature plasma is produced. A schematic of the original source design is shown in Fig. 4.6. Gas flows (12–48 m/s) through the needle electrode and supplies the media in which the discharge occurs. A glass plate is placed between the needle and counter electrodes and serves both as the dielectric material and sample substrate. The technique has been used for amino acid analysis, where mostly protonated species were observed with an LOD of 3.5 pmol. A high reproducibility was observed for the analysis of alanine (relative standard deviation (RSD) <6%) [110]. An alternative design, but similar in that it uses

Figure 4.6 A schematic of the DBDI source in which a dielectric material is placed between a counter electrode and a needle electrode. An alternating voltage is applied to the needle electrode, creating a low electrical discharge that drives desorption and ionization of analyte. *Source:* Used with permission from Ref. 110.

a dielectric material to create a low temperature discharge, has recently been reported and termed *low temperature plasma* (LTP) probe [113].

PADI utilizes a lower voltage peak to peak (300 V) than DBDI to create a stable glow discharge, resulting in a cold plasma with relatively low ion energies (5–20 eV) [111]. As a result, PADI has distinct advantages for analysis of thermally labile analytes when compared to higher energy corona discharge techniques. The glow discharge is easily visible to the eye and aids in alignment of the source, sample, and inlet of the mass spectrometer. A schematic of the source and a picture of the discharge are shown in Fig. 4.7. The nonthermal plasma is around 1 mm in diameter and extends up to 10 mm from the source. Desorption of analyte is thought to occur through a combination of energy transfer from metastable helium and ion impact, while ionization is attributed to proton transfer reactions from ionized water clusters. PADI has shown similar results when compared to DESI for the analysis of a variety of pharmaceuticals; however, a lower degree of fragmentation and higher signal intensity were observed from PADI-generated mass spectra [111].

4.5 AMBIENT LASER-ASSISTED DESORPTION ELECTROSPRAY IONIZATION TECHNIQUES (ELDI, MALDESI, LAESI, IR-LADESI)

The final group of ambient techniques discussed in this chapter combines the favorable characteristics from both MALDI and ESI into one-source design and are often referred to as *hybrid methods*. For example, MALDI produces singly charged ions, while ESI produces multiply charged ions. Multiple charging affords more efficient fragmentation of large biological molecules; thus, ESI-produced ions are readily amenable to top-down [114,115] and bottom-up characterization [116,117] methods, including CID [118], ECD [119] and ETD [120]. However, MALDI allows for direct analysis [121,122] and imaging applications [123,124], while ESI does to a far lesser degree. As a result, a source design that embodies both characteristics of MALDI and ESI would have a significant impact spanning the realm of the biological sciences.

A representative setup of the techniques discussed in this section is shown in Fig. 4.8. First, a laser ablates material deposited onto a stainless steel plate and a mixture of neutrals, ions, and other charged particles are created. This process is analogous to atmospheric pressure matrix-assisted laser desorption ionization (AP-MALDI) [125,126]. As shown in Fig. 4.8, the sample plate is placed between and slightly lower than the inlet of the mass spectrometer and the ESI emitter. Following laser ablation, neutral gas molecules are post ionized through fusion with ESI-charged droplets. Once the gas molecules are solvated, the mechanism(s) of ionization are believed to be highly similar to ESI [127].

Laser ablation followed by post-ESI of neutrals was first reported by Shiea and coworkers in 2005, in which they observed multiply charged cytochrome *c* species [128]. They named this process electrospray-assisted laser desorption ionization (ELDI). This technique was in part based on the same group's developments of fused droplet electrospray ionization (FD-ESI), where they interacted with aerosols containing nonvolatile species with an ESI beam [129,130]. In the seminal reports of ELDI, it was demonstrated that an optimal protein signal was obtained without the addition of any organic matrix [131]. However, shortly after the first reports of ELDI, Muddiman and coworkers introduced MALDESI and stated that in their experiments an organic

Figure 4.8 (a-b) The setup of a typical laser-assisted desorption electrospray ionization experiment. The laser is focused via a series of lens and ablates material from a surface. Gas-phase molecules interact with charged ESI droplets and are ionized. (c) A close-up view of the setup. The sample is typically placed a few millimeters below the inlet of the MS capillary and ESI emitter. (d) The series of events used by Muddiman and coworkers for their MALDESI FT-ICR setup [127]. The ELDI source uses a UV wavelength laser with no matrix. The MALDESI source uses a UV laser with an exogenous organic matrix. Both LAESI and IR-LADESI utilize an infrared wavelength laser and for samples with sufficient water content no exogenous matrix is required. *Source:* Used with permission from Ref. 127.

matrix was required for a protein signal and as a result argued the technique's name should reflect the importance of the matrix [127]. More recent studies have reported similar findings that the addition of an organic matrix significantly increases signal quality [132]. Regardless, ELDI and MALDESI have been used to analyze both condensed and liquid samples [132,133]. The implementation of liquid MALDESI requires a slightly different configuration in which no electrospray post ionization is used and interestingly the charging of the sample containing the liquid droplet occurs through an application of a high voltage to the stainless steel sample plate. Several smaller or daughter droplets are created on laser ablation and then are sampled by the mass spectrometer [133]. Ionization is believed to then follow similar ESI pathways. Muddiman and coworkers also demonstrated that one can electrochemically oxidize analytes using the liquid MALDESI setup [133].

Several applications of both the ELDI and MALDESI techniques have been reported. ELDI has been used for the direct detection of intact proteins in blood, tears, saliva, and serum [131]; analysis of illicit drugs [128]; direct interrogation of organic compounds separated by thin layer chromatography [134]; real-time analysis of organic reactions [135]; detection of inks in documents [136]; and various other species from

solid surfaces [137]. Similar to reactive DESI, reactive ELDI has been reported for real-time reduction of disulfide bonds by the addition of dithiothreitol (DTT) into the electrospray solvent. In addition, as observed in ESI [138,139], the addition of nitrobenzyl alcohol (NBA) to the spray solution afforded an increase in protein charge state for ELDI-generated mass spectra [140]. These experiments provide further support for the fusion of gas-phase neutrals/particulates with charged droplets as the underlying mechanism in ELDI/MALDESI. MALDESI has shown utility for the analysis of intact proteins, especially when coupled to high resolving power platforms where the monoisotopic mass of moderately high molecular weight species can be determined unambiguously [127,141]. Muddiman and coworkers have increased this accuracy by doping known species into the spray solution and utilizing these masses for internal calibration, affording mass measurement accuracies of intact proteins of <1 ppm. MALDESI has been shown to be relatively sensitive with detection of subfemtomole quantities determined using stable isotope-labeled and naturally occurring peptides [141]. Top-down sequencing of apomyoglobin has been demonstrated utilizing a hybrid LTQ-FT-ICR mass spectrometer [142]. In addition, MALDESI has been reported for the direct analysis of lipids from egg yolk, carbohydrates from milk, and O-linked glycans released via chemical methods from heavily glycosylated mucin, effectively demonstrating direct analysis of three out of the four classes of biological molecules (i.e., proteins, lipids, carbohydrates) [142]. A report describes the most recent version of the MALDESI source, which is equipped with a high repetition rate laser affixed to a vibrationally damped breadboard. The sample target is placed on a computer-controlled motorized stage, allowing full interrogation of the sample plate with 35 nm resolution. A complete list of parts, vendors, and in-house fabricated components are described for anyone interested in replicating the source [143].

Both MALDESI and ELDI setups were developed using a UV laser; however, Vertes and coworkers introduced LAESI in 2007 [144], which, in principle, is similar to ELDI and MALDESI but utilizes an Er:YAG infrared wavelength laser. Through independent investigations and concurrent to the development of LAESI, Rezenom *et al.* reported an analogous technique utilizing an infrared laser and coined the name infrared laser-assisted desorption electrospray ionization (IR-LADESI [145]. Muddiman and coworkers coupled both 2.94- μm [142] and 10.6- μm infrared lasers [146] to the MALDESI platform and called the technique *infrared matrix-assisted laser desorption electrospray ionization* (IR-MALDESI) [142]. More recently, Loo and coworkers reported the coupling of an optical parametric oscillator (OPO) infrared laser with their ELDI setup and referred to the technique as *infrared electrospray laser desorption ionization* (IR-ELDI) [147]. Regardless of the overabundance of acronyms describing the similar techniques, several unique advantages exist for implementing an IR laser. First, infrared radiation has a sampling depth of $\sim 1\ \mu\text{m}$, which is several orders of magnitude larger than a UV laser, and as result a more substantial amount of material is removed from the sample plate on laser ablation [148,149]. The ionization efficiency of infrared radiation is low, which explains the low sensitivities of IR-MALDI compared to UV-MALDI. This phenomenon should be directly applicable to these postionization techniques [149]. Also and perhaps the most significant advantage for biological analyses (e.g., tissues, plasma, *in vivo*) is that water exhibits a strong infrared absorption between 2.8 and 3.2 μm and thus no exogenous matrix is required for sensitive analysis. IR laser ablation with ESI post ionization has been used for analysis of proteins [142,144,145,147], lipids [142,144], carbohydrates [142], pharmaceuticals

[145], metabolites [145,150], and profiling of single cells [151]. LAESI has shown its potential for imaging MS [150,152–154].

4.6 REMOTE SAMPLING

These ambient ionization sources are generally designed such that the sample is in close proximity to the atmospheric interface of the mass spectrometer. This closeness undoubtedly aids in the collection and subsequent detection of ions; however, it limits the location and geometry of the sample. One can envision using these techniques to generate ions several feet from the mass spectrometer and then transporting them to the instrument for subsequent detection. This decoupling of the ion source and mass spectrometer in space would mitigate the need for any sample manipulation (i.e., transporting the sample). Areas of applications include national security (e.g., screening of explosives), pharmaceuticals, and environmental. This remote sampling of the analyte has been accomplished via different but effective ways in the literature. Cooks and coworkers increased the inlet capillary length and were able to detect ions from as far as ~ 10 ft away from the mass spectrometer [108,155]. This setup, shown in Fig. 4.9, was used for detection of explosives, pharmaceuticals, illicit drugs, and peptides [108,155]. An alternative design, shown in Fig. 4.10, utilized a commercial air ejector to transport DESI-generated ions from the point of formation to the MS inlet via a flexible polyethylene tube [156]. A vacuum, created by the flow of nitrogen gas through the air ejector, enabled the detection of dyes, polymers, and peptides from as far as 3 feet away from the inlet. Both setups were relatively sensitive, with detection limits reported in the low nanogram range for both designs. The setup shown in Fig. 4.10 required the purchase of an inexpensive device and was coupled to a flexible polypropylene tube with no modification to the MS inlet, whereas the setup illustrated in Fig. 4.9 incorporated a rigid stainless steel capillary and required minor modifications to the MS interface. Further comparisons are not available at this time because of insufficient information.

Instead of remotely transporting *ions*, Dixon *et al.* described the use of an air ejector for transporting either solid *particulate* or *neutrals* created by laser desorption and interacting them with an ESI beam and called this process remote analyte sampling, transport and ionization relay (RASTIR) [157]. Small proteins (<10 kDa) were laser desorbed from a stainless steel plate and transported to the mass spectrometer for

Figure 4.9 The MS capillary can be simply extended up to ~ 10 feet to remotely analyze samples.

Figure 4.10 Analytes are transferred to the mass spectrometer via the use of an air ejector. Nitrogen flow through the device creates a negative pressure (i.e., vacuum) and transfers DESI- or ESI-generated ions to the mass spectrometer. The relative size of the device in relation to a penny is displayed (center). *Source:* Used with permission from Ref. 156. (See color insert.)

Figure 4.11 A schematic of ND-EESI setup. High pressure nitrogen gas desorbs volatile species from the surface and the analyte-containing gas stream is then mixed with the desolvation gas for ESI. Ionization occurs via the fusion of gas molecules with charge ESI droplets. *Source:* Used with permission from Ref. 158.

subsequent ionization by fusion with ESI beam and detection by LTQ-FTI-CR-MS. Multiply charged spectra were observed and mechanisms of ionization were believed to be similar to ELDI/MALDESI. Zenobi and coworkers simply used high pressure nitrogen gas to desorb volatile metabolites from the surface and then merged the analyte-containing gas stream with the normal desolvation line of ESI and termed this neutral desorption extractive electrospray ionization (ND-EESI) [158]. Using principal component analysis (PCA) analysis, it was demonstrated that one could readily differentiate frozen meat by the metabolomic profiles using ND-EESI. In these studies, metabolites were desorbed and then transported to the mass spectrometer across a distance of ~ 4 feet (Fig. 4.11). The ultimate goal of these studies is the development of an analytically robust method to decouple the sample and mass spectrometer in space for any number of applications ranging from national security, tissue imaging, *in vivo* analysis, pharmaceuticals, and environmental analysis.

4.7 APPLICATIONS

This chapter, thus far, has discussed the mechanisms, setups, and limitations while briefly summarizing the applications of several of the more widely used ionization techniques for ambient MS. Table 4.1 summarizes the attributes of each technique and provides a quick reference guide for the reader. In this table, the techniques are grouped together in their respective class as described (see above). The conclusion of this chapter consists of an in-depth discussion of some of the more pertinent applications of these ambient techniques including explosives, absolute quantification, pharmaceutical analysis, and imaging MS.

4.7.1 Explosives

Trace detection of explosives is a growing area of interest because of the increasing concern surrounding national security. Ion mobility spectrometry (IMS) is one of the more widely used detection methods for explosives [159,160] and is currently utilized in airport checkpoints around the world. Although IMS detection is rapid, relatively sensitive, and performed at atmospheric pressure, the technique suffers from poor linearity and poor selectivity, and hence difficulties exist in the identification of species in complex mixtures. Several reports exist on the rapid analysis of explosives from different surfaces by ambient ionization MS. This is most likely due to the combination of several factors including (i) increased (post 9/11) security concerns at airports and other highly populated venues, (ii) the unparalleled molecular specificity and sensitivity of MS, and (iii) the capability to conduct open air ionization from a variety of surfaces with limited to no sample preparation leading to fast analysis times (<10s) [44].

Explosive analysis was demonstrated in the first report of DESI when 1,3,5-trinitro-1,3,5-triazinane, commonly referred to as *RDX*, was detected in the negative ion mode from a leather surface [28]. The leather reproduced a real-life surface (e.g., luggage) at an airport. The ability to analyze various nonconducting surfaces is critical for explosive analysis because of the diverse nature of the surfaces from which these analytes are potentially derived. Several other explosives including octahydro-1,3,5,7-tetranitro-1,3,5,7-tetrazocine (HMX), 2,4,6-trinitrotoluene (TNT), pentaerythritol tetranitrate (PETN), triacetone triperoxide (TATP) [46] and composition 4 (C4) have been detected by DESI and DAPCI-MS from paper, glass, plastics, skin [47], and even prints derived from a finger that had come into contact with C4 [44]. Owing to the high electron affinities of the nitro or nitrate functional groups characteristic of many explosive compounds, most are more effectively ionized in the negative ion mode via electron capture or by doping in salts to form stable adducts. By doping HCl into the DESI spray, referred to as *reactive DESI*, Cooks and coworkers observed a 10-fold improvement of the LOD of RDX, allowing the detection of 10 pg from several surfaces [44]. Other explosives have shown similar detection limits (100 fg–10 pg) when analyzed as pure compounds via reactive DESI mode [87,107]. These sensitivities should be adequate for real-world explosive applications, as a recent study indicated that as great as microgram amounts of explosive are present in fingerprints after someone recently handled the plastic-bonded explosive C4 [161]. Besides DESI and DAPCI, several other ambient techniques including DBDI [162] and DART [163] have shown the ability to detect explosives from real-world surfaces with similar analytical performance to DESI.

TABLE 4.1 A Summary of Ionization Techniques

Technique	Ionization Mechanism(s)	Comments	Molecular Weight Range	Multiple Charging	Reported Applications	Seminal Work
Desorption electrospray ionization (DESI)	Desorption through solvation of analyte ESI-like ionization	Initiated the development of novel sources	<66 kDa ^a	Yes	Pharmaceuticals, explosives, metabolite, peptide, and proteins	2004 [28]
Desorption sonic spray ionization (DeSSI) or easy ambient spray ionization (EASI)	Statistical fluctuations of charged species in solvent droplets–proton transfer	No voltage is applied	<1500 Da	No	Pharmaceuticals, fatty acids, dyes, fuels	2006 [75]
Desorption atmospheric pressure photoionization (DAPPI)	Interaction through dopant ionized molecules	Ionization of low proton affinity analytes	<1000 Da	No	Pharmaceuticals and small molecules	2007 [89]
Direct analysis in real time (DART)	Protonated water clusters	Ionization of both polar and nonpolar species	<1500 Da	No	Pharmaceuticals, counterfeit drugs, explosives, metabolites	2005 [91]
Atmospheric pressure solids analysis probe (ASAP)	Thermal desorption corona discharge ionization	Modification made to commercially available sources	<1000 Da	No	Polymers, metabolites	2005 [105]
Desorption atmospheric pressure chemical ionization (DAPCI)	Corona discharge of volatile solvent vapors	Complimentary to DESI	<1000 Da	No	Explosives, metabolites	2005 [29,107]

Plasma-assisted desorption ionization (PADI)	Low temperature discharge	Softer ionization than corona discharge methods	1000 Da	No	Pharmaceuticals and metabolites	2007 [111]
Dielectric barrier discharge ionization (DBDI)	Low temperature discharge	Uses a dielectric material to create a low temperature discharge	<1000 Da	No	Amino acid analysis, explosives	2007 [110]
Electrospray-assisted laser desorption ionization (ELDI)	Laser desorption followed by secondary electrospray ionization	No matrix is used (UV laser)	<66 kDa	Yes	Proteomics, pharmaceuticals, small molecules	2005 [128]
Matrix-assisted laser desorption electrospray ionization (MALDESI)	Laser desorption followed by secondary electrospray ionization	An organic matrix is used (UV laser)	<66 kDa	Yes	Proteomics, glycomics, lipids	2006 [127]
Laser ablation electrospray ionization (LAESI)/IR LADESI	Laser desorption followed by secondary electrospray ionization	IR laser for desorption (water rich sample)	<66 kDa	Yes	Proteomics, tissue imaging, metabolomics, lipids	2008 [144,145]

^aDESI becomes significantly less sensitive at MW > 20 kDa

The majority of these reports have been qualitative in nature; for a rapid screening method, the simple, fast, unambiguous identification of an explosive will normally suffice. However, there are some applications where determining the absolute amount of an explosive present would be useful. Obtaining quantitative information from these ambient ionization techniques is difficult for numerous reasons and as a result is less often reported in the literature. These difficulties stem mainly from the varying degrees of ionization efficiencies of different analytes, morphology of the sample, and the synthesis and incorporation of a stable isotope-labeled (SIL) species into the sample deposited on the surface. Label-free methods (e.g., absolute intensity) could circumvent this limitation; however, analyte suppression and the nonuniform distribution of analyte on a surface [36], similar to the sweet spot effect in MALDI, makes this method less robust as well. Nevertheless, under careful optimization Cooks and coworkers have performed absolute quantification of RDX via the construction of a 5-point calibration curve. Triplicate measurements of the calibration points showed a relative standard deviation of <3% and analysis of an unknown sample gave an ~2% error in the correct amount of material. These results are encouraging for simple mixtures, but in experiments where the complexities differ between the calibration standards and actual samples suppression of analyte may occur and would affect the accuracy of the results.

The area of the sampling in DESI is typically <2–3 mm² and the effective ionization region is ~0.1 mm² [70]. A major limitation in screening of large objects is the relatively low amount of surface area that is actually sampled compared to the large amount of surface area that needed to be screened (e.g., suitcase, clothes, etc). The area sampled in DESI is largely a function of flow rate, surface characteristics, tip-to-surface distance, and the diameter of the spray capillary [29]; by optimizing these parameters one can significantly increase the sampled spot area, but this may lead to less than optimal desorption and ionization performance. Some have developed large-area desorption DESI devices by implementation of three DESI sprayers [29,108] or by utilizing a large-area DESI source [164]. These devices have increased the sampling area of DESI to ~3 cm²; however, still further advancements are warranted for streamlining the interrogation of samples with large surface areas.

4.7.2 Pharmaceuticals and Counterfeit Drugs

Another impact area for these ambient ionization sources is in the pharmaceutical industry, where increasing competition and regulatory pressure have required companies to enhance throughput efficiency. Currently, for quality control and drug discovery experiments, active pharmaceutical ingredients (APIs) from drug formulations are extracted, purified via chromatographic methods and analyzed using UV-vis or MS detection. These steps are time consuming, and increase the amount of time to mature products from bench top to bedside. Methods to obtain both qualitative and quantitative information from drug formulations with limited to no sample preparation would be of significant importance in an environment where throughput and profit are often directly related.

Several ambient techniques have been used for analysis drug tablets. Cooks and coworkers reported the use of a home-built variable speed moving belt in which samples were placed on the belt and analyzed by DESI [57]. This conveyor belt apparatus simulated a real pharmaceutical production line with the last step in production being

DESI-MS analysis. Utilizing this setup both qualitative and semiquantitative information were obtained from tablets, liquids, and ointments at a rate as high as three samples per second. Acetaminophen, acetylsalicylic acid, and caffeine were all detected from an Excedrin tablet and various components were detected from a Centrum multivitamin. Williams *et al.* demonstrated the ability to obtain high mass accuracy DESI-MS spectra using a novel dual ion source for polarity switching accurate mass detection of ingredients [165]. A reference ion used as a lock mass was infused into a separate MS inlet, while DESI was performed and afforded mass errors of active ingredient <2 mTh. In addition, the study showed the utility of polarity switching in obtaining information from pharmaceutical ingredients that preferentially ionized in either positive or negative ion mode. This setup increased throughput further, since the need to analyze the sample twice in both positive and negative modes was negated. DeSSI demonstrated increased abundance of low molecular weight analytes derived from pharmaceutical formulations when compared to DESI. This was attributed to suppression of analyte signal by various water clusters/matrix ions that are observed in the low molecular range when performing DESI [166].

The high throughput capabilities of these techniques were exemplified in a study of liquid formulations by DART using a 96-well plate. The process was fully automated and the ends of glass melting point capillaries were dipped into the analyte solution and then placed between the DART source and mass spectrometer by an autosampler. This setup afforded a high linearity; however, deviations were observed at high concentrations and were attributed to dimer formation. DART affords a complimentary mode of ionization compared to DESI and ESI, a clear advantage in the analysis of low polarity analytes in formulations [166].

An interesting application of these techniques is in the high throughput screening of counterfeit drugs, which is a growing problem in both developing and developed countries. Fernandez and coworkers have performed extensive research in the development of ambient methods for the qualitative and quantitative analysis of pharmaceuticals that fight malaria; a disease that claims over 1 million lives each year [167]. Often, these drugs are counterfeited and the fraudulent types mimic both the tablets and packaging of the genuine drugs, making it difficult to distinguish between the two and require more sophisticated measurement methods to identify the counterfeit tablet. Both DART [97] and DESI [56,97] have been reported for the qualitative identification of the active ingredient artesunate, one of the more commonly counterfeited antimalarials. Unexpected ingredients such as acetaminophen [167] are often found in these counterfeit antimalarials, possibly to deceive less specific analytical methods and/or provide temporary relief of symptoms associated with the disease. More recently, counterfeits containing low sub-therapeutic levels of the active ingredient artesunate have been discovered. These findings are significant as they warrant robust quantitative screening methods to determine the quality of tablets, and the widespread distribution of these drugs could render oral artesunate ineffective because of the development of genetically resistant strains.

Obtaining absolute quantification information from these ambient techniques is difficult for reasons discussed (see above). However, Fernandez and coworkers developed a method using a SIL version of artesunate and reactive DESI for the absolute quantification of artesunate in counterfeit antimalarials [168]. One of the major problems associated with using SIL labels of target analytes is obtaining an evenly distributed

Figure 4.12 Method used for absolute quantification of antimalarials by reactive DESI-MS. *Source:* Used with permission from Ref. 168.

amount of analyte on the surface of a solid tablet. This is dependent on surface porosity, roughness, and solvent used for deposition. Several methods of SIL deposition were explored in the initial stages of method development, including doping the SIL into the ESI solvent and pneumatically spraying it onto the tablet. It was found that by simply pipetting the SIL on top of the tablet's surface and allowing it to dry led to the most robust results. After allowing the solution to dry on the tablet's surface, it was subjected to DESI-MS analysis. A high precision (7.9% RSD) for the ratio of heavy versus light artesunate was determined across various areas of the tablets, indicating an evenly distributed stable isotope label form of artesunate. The ratio was found to be independent of flow rates, nebulizer gas pressure, and geometric variables; however, the hardness of the tablet was found to have a dramatic effect. This procedure for SIL deposition and DESI-MS analysis is summarized in Fig. 4.12.

A calibration curve of various concentrations of artesunate tablets (0.02–0.35 mg artesunate/mg of tablet) demonstrated excellent linearity ($r_2 = 0.9985$). Test samples were used for cross validation of the method and a correlation of 0.9971 was observed. These results indicate the potential of DESI-MS for absolute quantification of artesunate in antimalarials. However, a problem arose when attempting to obtain quantitative information from tablets with different hardness than from which the calibration curve was created. Table 4.2 shows the absolute amounts of three different tablets that were obtained in the field. A large error in absolute amount was observed and attributed to the various degrees of hardness of the tablet. After correcting for this variable, an approximate 6% error in the accuracy was achieved on average. Exact concentrations of artesunate in these tablets were determined by traditional high performance liquid chromatography (HPLC) methods and these values are also shown in Table 4.2. These encouraging results emphasize the importance of surface properties on obtaining reproducible quantitative results and indicate the potential for high throughput quantitative analyses from solid dosage products.

4.7.3 Imaging Mass Spectrometry

Imaging MS is a promising arena because of the ability to determine the identity, abundance, and spatial arrangement of species on surfaces, specifically biological

TABLE 4.2 A Summary of the Absolute Quantification of Artesunate in Antimalarials by DESI-MS. The Second Column is Corrected for Tablet Hardness

Sample	Artesunic Acid (mg/tablet)		HPLC
	Predicted with no Correction	Predicted with Correction	
Tablet 1	73 ± 4	58 ± 3	53 ± 2
Tablet 2	73 ± 5	58 ± 4	56 ± 2
Tablet 3	68 ± 4	53 ± 3	50 ± 2

tissues. The potential of imaging MS has long been recognized and dates back to the early 1970s when the first molecular imaging experiments using laser desorption were reported [169]. Almost 30 years later, tissue imaging of proteins by MALDI evolved from the direct analysis of biological specimens was reported by Caprioli [170,171]. Currently, most imaging experiments utilize vacuum techniques SIMS or MALDI and each offer different capabilities [172–174]. SIMS affords the highest attainable resolution of any ionization technique with submicron readily achievable [175]; however, the technique is limited to small molecules/peptides and instrumentation is expensive. MALDI is capable of imaging large molecules, such as proteins, with low micron resolution attainable (i.e., 25–100 μm). The ability to conduct open air ionization, as opposed to *in vacuo*, facilitates the analysis of samples in their native state without detrimental sample preparations/manipulations while also increasing the breadth of samples amenable to interrogation. In addition, for protein imaging studies, MALDI produces only singly charged species, which limits these experiments to relatively low resolving power TOF instruments.

Some of the early investigations of direct molecular profiling using these ambient techniques were reported by Cooks and coworkers. In these preliminary studies, they showed the utility of DESI to interrogate plant tissue with absolutely no sample preparation. Various alkaloids were detected from the leaves, seeds, stems, roots, and flowers derived from jimsonweed, poison hemlock, and deadly nightshade [30]. Similar mass spectra and signal intensities of alkaloids were observed for DESI-MS when compared to LC-ESI-MS, albeit the latter requiring significant sample extraction, preparation, and separation of species. In 2005, the same group reported direct molecular profiling of lipids from rat brain, mouse liver, and metastatic human liver adenocarcinoma tissue. A notable finding from these studies was that the normalized abundance of various lipids could be used to distinguish normal versus tumor regions of liver tissue [176]. More recently, other ambient ionization techniques have shown potential for direct biological profiling. DART has been used to detect alkaloids from hairy root plant. Spectra of various alkaloids species were readily obtained by simply holding the tissue in between the source and inlet of the mass spectrometer [102,103]. In addition, DART was utilized to profile whole bacterial cells [96] and volatile organic compounds from eucalypts [177]. Larsen and coworkers investigated the inhibition of the ergosterol pathway in fungal cells via the ASAP method [106]. MALDESI has been utilized for the direct profiling of lipids in egg yolk [142], while LAESI has shown the potential for profiling of plant tissues and whole cells. All these examples demonstrate

Figure 4.13 Atmospheric pressure imaging of lipids in a coronal section of rat brain tissue by DESI-MS. *Source:* Used with permission from Ref. 178. cc, corpus callosum; LV, lateral ventricles; ac, anterior commissure. (See color insert.)

the great potential of these exciting new ambient ionization methods for direct profiling of tissue.

Although several techniques have been reported for tissue profiling, imaging applications are limited to techniques in which there is a finite area of desorption on the surface. For example, ASAP is not well suited for imaging experiments since the area of desorption and thus mass spectra analysis are not well defined. In addition, for imaging of peptides and proteins, a technique capable of desorption and ionization of nonvolatiles is required.

Figure 4.13a and b shows the mass spectral images of phosphatidyl serine (m/z 810) and myristoleic acid (m/z 225) obtained from a 4- μm coronal section of rat brain tissue in negative ion mode using DESI [178]. Phosphatidyl serine is shown to be concentrated in the region corresponding to the white matter in the brain and significantly less distributed in other parts, while the selected ion image of myristoleic acid shows this species much more evenly distributed throughout all regions of the tissue. Other structural features were readily discerned from these images, including the lateral ventricles and the anterior commissure. In these experiments, the lateral resolution was $\sim 400\ \mu\text{m}$, which is typical for an optimized DESI experiment [179]. Recently, the three-dimensional image of lipid distributions in rat brain tissue was reported by DESI. In these experiments, the 3D images were constructed via the careful acquisition of several 2D images [180].

LAESI has also been used to image rat brain tissue [154]. Figure 4.14 displays distributions of several molecular species corresponding to metabolites and lipids across a 100- μm coronal section of tissue. Mass spectra were obtained by ablating the tissue with mid-infrared pulses (2940 nm) at a repetition rate of 20 Hz. Using this setup, Vertes and coworkers were able to achieve a 200- μm lateral resolution. It is important to note that no exogenous matrix was required since water absorbs IR radiation and is intrinsically found in tissue. To prevent drying of the sample and/or analyte mobilization, the tissue was kept frozen during the experiments by placing it on a cooling stage. As with DESI imaging of brain tissue, LAESI revealed several species

Figure 4.14 Atmospheric pressure imaging of lipids and metabolites in a coronal section of rat brain tissue by LAESI-MS. Species identified with high correlations are as follows (a) ethanolamine with (b) creatine; (c) γ -butyrolactone with (d) γ -aminobutyric acid and/or 2-methylalanine; (e) spermine with (f) PC(35:4) and PE(38:4); (g) cholesterol- H_2O with (h) plasmalogens PC (O-33:3) and/or PE(O-36:3); and (i) heme with (j) α chain of hemoglobin. The plots of the highly correlated pairs are shown in the third column and colocalization is indicated by dark areas. *Source*: Used with permission from Ref. 154. (See color insert.)

that were localized in specific parts of the matrix. For example, Fig. 4.14c reveals that γ -butyrolactone is highly concentrated in the septal complex, while Fig. 4.14e shows the spermine ion to be more evenly distributed through the whole tissue except the corpus callosum. Using simple cross correlation statistics of all possible pairs of ion intensities distributions, Vertes showed the ability to correlate species based on their localization within the tissue. Not all analytes correlated well to one another; however, some showed a high correlation as shown in Fig. 4.14. The colocalization images of the paired species are shown in the last column of Fig. 4.14. These plots are validated by investigating the relationship of both the heme group and the α -chain of hemoglobin. Since both are derived from the same species, a high correlation is expected and is

shown in Fig. 4.14i and j. The identities of all species in these images are given in the caption of Fig. 4.14.

It is difficult to compare DESI and LAESI for imaging applications because of the relatively early developmental stages of both ionization techniques to imaging MS; however, the use of a laser for desorption instead of a solvent jet provides apparent advantages. Although, currently DESI is commercially available [181] and simpler to implement than LAESI, DESI is molecular weight limited and analysis of proteins larger than 20 kDa has proven difficult [61]. This phenomenon limits the technique's capabilities for protein imaging applications. The radius of the desorption area of the DESI plume on the surface is considerably larger than that which can be achieved with a laser [143] and often ill defined [70]. In addition, careful optimization of DESI spray on the surface is required to avoid excessive splashing [70], which theoretically could lead to mobilization of analyte on the tissue and inaccurate mass spectral images. Regardless, numerous reports exist for both DESI [41,54,178,180,182,183] and LAESI [150,152–154] for imaging applications, and only future investigations will decipher the full potential and limitations of each technique for these type of experiments.

4.8 FUTURE OUTLOOK

There has always been an active area of interest in the development of ionization methods for MS; however, in the past decade the intensity of this pursuit has significantly increased. This growing field of ambient ionization is largely a result of the technological advances in instrumentation, which has led to increased sensitivity and specificity and the emerging number of scientific problems that can be addressed using MS. In addition, the majority of vendors now offer commercial instrumentation with API interfaces as opposed to vacuum, which are easily modified to accommodate the different ambient techniques. Applications of these techniques have dominated the literature with far less studies covering mechanistic characteristics. A more in-depth understanding of desorption and ionization mechanisms is needed and will likely direct and shape future applications of each technique. For pharmaceutical applications, where analytes of interest are at a high overall concentration, these techniques are near ready to make an impact at a qualitative level. For studies involving absolute quantification, further research is needed in several fundamental areas before data can be determined in a high throughput manner with any degree of confidence. In biological applications and biomarker discovery experiments where physiologically relevant species are at a low level of concentration, the sensitivity of these techniques must be improved. This could partially be circumvented by increasing the collection efficiency of ions or charged droplets at the inlet of the mass spectrometer via the implementation of an aerodynamic device [184–187].

Despite these yet-to-be-achieved goals, the future of ambient ionization is quite encouraging and exciting. This can simply be shown by the large advancements that have been made in this arena in a relatively short period of time. Most of these techniques are in their mere infancy of existence. Fig. 4.15 displays a plot of the number of papers published as a function of year for FAB, MALDI, ESI, and the ambient techniques discussed herein. Interestingly, the number of reports of all of these techniques is similar to the number of reports of FAB in 2009 and reminiscent of ESI and MALDI in the early 1990s. As a result and similar to the developmental

Figure 4.15 A plot of papers published as a function of year using ESI, MALDI, FAB, and new ambient ionization techniques. This graph was created using ISI Web of Knowledge and the search terms: ESI-MS or electrospray ionization; MALDI-MS or matrix-assisted laser desorption ionization; FAB-MS or fast atom bombardment; and all of the ambient technique described herein. (See color insert.)

stages of ESI and MALDI, the ultimate impact of these techniques will only be realized through extensive research.

5.1 INTRODUCTION

Matrix-assisted laser desorption/ionization-mass spectrometry (MALDI-MS) burst on the scene in the late 1980s and has since revolutionized the field of MS. MALDI-MS is a viable MS approach for the characterization of biomolecules, synthetic polymers, petroleum and coal products, and inorganic and organic materials. The simplicity, speed, and performance features of MALDI-MS permit the characterization of compounds previously intractable to MS analysis.

While MALDI-MS has not been a traditional “first-choice” for pharmaceutical research [because of the widespread utilization of liquid-chromatography (LC)-based MS methods], one goal of this chapter is to introduce and highlight several areas where MALDI-MS provides clear and compelling advantages in the pharmaceutical analytical toolbox. To be sure, MALDI-MS is not considered here as a replacement for LC-based MS approaches, but instead is viewed as a powerful complement, especially in applications requiring high throughput analysis or the characterization of high molecular weight compounds.

This chapter is constructed to guide the reader through a brief history of MALDI-MS, recognizing its fundamental role in transforming not only modern MS, but a wide number of related disciplines, including those of interest in the pharmaceutical field. Next, the basics of MALDI-based instrumentation are covered with an emphasis on

the laser source and mass analyzer combination. The chapter continues by reviewing the basics of the MALDI matrix, describing necessary matrix properties and reviewing various matrix/sample preparation strategies. A discussion of matrix/analyte combinations of particular interest in the pharmaceutical field is also supplemented by an introduction into new approaches to MALDI-MS, including matrix-free approaches and the use of room temperature ionic liquids as matrices. The latter third of the chapter discusses approaches for obtaining structural information using a MALDI-based mass spectrometer, followed by selected applications of MALDI-MS in fields of particular interest to biopharmaceutical research.

5.2 HISTORICAL DEVELOPMENT OF MALDI-MS

Since the development of the laser as a high intensity source of light, there have been many investigations of the evaporation and ionization of solid materials by focused laser light [1]. Laser desorption (LD) became an effective method for producing gas-phase ions from nonvolatile low mass thermally labile organic salts during the 1970s and 1980s [2–6]. In LD, the probability of obtaining a useful mass spectrum depends critically on the various physical properties of the analyte (e.g., photoabsorption, volatility, etc.). Furthermore, molecules with masses over ca. 1000 Da almost always produce only fragment ions.

LD-based approaches were not regarded as a viable technique for examining high molecular mass compounds until 1987 [7]. At that time, the research laboratories of Tanaka and Hillenkamp independently discovered a new approach that could couple LD with efficient sample ionization. Their key advance was the introduction of an excess of a light-absorbing compound, the matrix, that could be combined with the analyte of interest to yield intact molecular ions on laser irradiation. Specifically, the addition of ultrafine metal powder (UFMP) to analyte solutions in glycerol [8] and the cocrystallization of the analyte with an organic small molecule solution [9] revolutionized the area of MS by producing mass spectra of proteins of ca. 100,000 Da.

Tanaka *et al.* [8] changed the perception that LD cannot be used for high mass biomolecules without fragmentation, an achievement recognized by the Nobel Prize in Chemistry in 2002 [10]. A sample was made into a solution and dripped onto a sample holder. UFMP (cobalt powder of about 300 Å diameter) and glycerol were dissolved with organic solvents and also dripped onto the sample holder. This mixture was then vacuum dried for a short time to remove volatile compounds of the solution. The sample holder, with the sample, was then introduced into the mass spectrometer for analysis. A nitrogen laser was used for sample ionization. By this method, Tanaka and coworkers [8,11] were able to detect several high mass molecular ions (Fig. 5.1), for example, lysozyme (molar mass 14.3 kDa), chymotrypsinogen (molar mass 25.7 kDa), poly(propylene glycol) (PPG) (average molar mass 4 kDa), carboxypeptidase A (molar mass 34.4 kDa), bovine insulin (molar mass 5.7 kDa), cytochrome *c* (molar mass 12.3 kDa), and PEG20K (average molar mass ca. 20 kDa).

The method of sample preparation chosen by Karas and Hillenkamp was fundamentally different. Their long experience with LD led them to believe that often it was the substrate under a layer of organic material on a surface that absorbed the laser light, not the organic molecules themselves. In 1985, Hillenkamp and coworkers began to

Figure 5.1 Laser ionization mass spectrum of lysozyme from chicken egg white, molecular weight 14,306 Da. publish papers containing the hypothesis that large molecule ions could be produced by mixing the analyte with a matrix material that was chosen for its ability to absorb light [12,13]. This matrix material would absorb light, resulting in its ablation and, hopefully, to a coupled desorption of analyte molecule ions. The profound role of the matrix in driving the desorption process led to the designation of this approach as matrix-assisted laser desorption/ionization (MALDI). A variety of matrices were investigated, including tryptophan, nicotinic acid, 3-nitrobenzyl alcohol, and 2-nitrophenyloctylether, and the results published were promising, but not spectacular [7].

The breakthrough for MALDI as applied to polypeptides came with the discovery that nicotinic acid had special properties for large polypeptides [9,13,14]. A Nd:YAG laser at 266 nm was used. Nicotinic acid is a solid at room temperature, with a low vapor pressure (but a tendency to sublime) and a high absorption coefficient at 266 nm. When aqueous solutions of a protein and nicotinic acid were mixed and a droplet of this mixture was dried, the deposit formed had the properties they had sought. They reported the ability of MALDI-MS to generate a large number of intact molecular ions as well as dimers and doubly charged molecular ions of proteins in the mass range above 10,000 Da, stable at least up to time lengths of about a millisecond. In all cases, singly charged molecular ions were the base peaks and no fragmentation was observed above 1000 Da (Fig. 5.2) [9].

The Hillenkamp–Karas approach rapidly underwent essential developments over the subsequent years, resulting mainly in the change of the preferred laser wavelength from the originally used 266 nm to 337 nm, as well as the discovery of at least a dozen new good “chemical matrices.” Hillenkamp defined the “chemical matrix” as a preferentially organic compound that is either a liquid or that dissolves homogeneously in a suitable solvent and that *simultaneously* acts as the light absorber and interacts

Figure 5.2 (a) Matrix-UVLD spectrum of β -lactoglobulin A, mass range of molecular ion region, 50 accumulated individual spectra. (b) Matrix-UVLD spectrum of bovine albumin, mass range of molecular ion region, 100 accumulated individual spectra. *Source:* Figures reproduced with permission from "Laser desorption ionization of proteins with molecular masses exceeding 10000 Da." with the analyte in the ion-formation process [15]. A large variety of compounds has been empirically tested in the past for their suitability as a matrix. Today, analysts commonly make their choice from a relatively small number of established "chemical matrices," for example, from benzoic or cinnamic acid derivatives. The actual choice depends on the type of the sample being analyzed with only a few matrix compounds

[e.g., 2,5-dihydroxybenzoic acid (2,5-DHB)] proving useful for a number of different compound classes [16].

5.3 OVERVIEW OF MALDI-MS

It has nearly been 25 years since those seminal demonstrations of soft ionization by LD, and the intervening years have generated a substantial literature surrounding the fundamentals of the MALDI process, instrumentation developments (both in lasers and mass spectrometers), sample preparation methods, matrix discovery, and applications in numerous fields. For more comprehensive reviews of that literature, the reader is invited to seek out additional publications in the area [17–28].

Biomolecule analysis by MALDI-MS requires a MALDI mass spectrometer, typically a time-of-flight mass spectrometer (TOF-MS), a suitable matrix that depends on the analyte class of interest, and appropriate sample preparation. Below, each of these requirements are briefly examined, with a focus toward those items or approaches most commonly used in a bioanalytical laboratory.

5.3.1 MALDI-MS Instrumentation

5.3.1.1 MALDI Laser Source. Among the various commercial vendors of MALDI-based mass spectrometers, systems are differentiated by laser wavelength, repetition rate, and laser spot size. The pulsed nitrogen laser ($\lambda = 337$ nm) and the frequency-tripled Nd:YAG laser ($\lambda = 355$ nm) are the most common lasers used in UV-MALDI-MS [29]. IR lasers were used in some early studies of MALDI-MS, and have been explored as alternatives to UV lasers [30–32], primarily because of the larger option for matrices and/or sample desorption in the IR range. However, while IR lasers are more successful in characterizing higher molecular weight samples than are UV lasers for specific applications, such as nucleic acids [33,34], in general the majority of MALDI-based applications are conducted using UV lasers.

Operationally, laser fluences on the order of 10^6 to 10^7 W/cm² are common in MALDI-MS. The best results are achieved by working at or just above the threshold irradiance necessary to generate analyte signal. To achieve the appropriate laser irradiance, some means of attenuating the laser output are typically employed and are common accessories on commercial instruments. Lasers are available in a wide range of repetition rates, ranging from the Hz range for nitrogen lasers up to modern Nd:YAG lasers with rates >1000 Hz. Spot sizes from 5 up to 150 μ m are available, depending on the beam focusing technology used.

5.3.1.2 MALDI Mass Analyzers. The most common instrument configuration is the MALDI ion source coupled to a TOF mass analyzer. The sensitivity, resolution, and mass accuracy depend on the particular TOF used. A detailed discussion of TOF-MS can be found in the chapter titled of this volume. Here, we briefly discuss the varieties and operational characteristics of these mass analyzers, highlighting their coupling to MALDI ion sources.

Standard TOF mass analyzers are available in two configurations, a linear time-of-flight (L-TOF) or a reflectron TOF (re-TOF). In L-TOF, ions are accelerated for less than a few hundred nanoseconds. Once ions leave the acceleration region and

enter the field-free region, any fragmentation that occurs will not be detected. In this case, less fragmentation is observed in L-TOF as this instrumental configuration cannot differentiate the parent and fragment ions. A significant disadvantage of the L-TOF is that it cannot reduce peak broadening occurring from the initial velocity distribution of ions. Typically, poor resolution and mass accuracy are the result.

A common instrumental approach for increasing the resolution and mass accuracy in TOF is the addition of an electrostatic mirror at the end of the flight tube that reverses the ion's direction and refocuses the ion toward the detector. The re-TOF mass analyzer effectively doubles the path length of the ion, yielding longer flight times and, hence, higher mass spectral resolution. In addition, the electrostatic ion mirror compensates for the initial energy spread of the ions, thereby improving focusing of ions of a single m/z more effectively at the detector, which improves instrumental mass accuracy.

All commercial MALDI-TOF systems are equipped with time-lag focusing, commonly referred to as *delayed extraction* (DE). This instrumental development was coupled to TOF as a means of reducing the initial velocity spread of ions while they are still in the accelerating region of the mass spectrometer, yielding improved resolution and lower mass measurement errors [35–37]. In the DE mode of operation, a second electrostatic gate is included in the ion source region. During the laser pulse, this electrode is held at a potential sufficient to prevent the acceleration of the laser-desorbed ions into the field-free region of the mass spectrometer. After a suitable delay period, which is mass dependent, the ions are then accelerated into the field-free region and analyzed as usual. In addition, to avoid detector saturation due to the matrix ions present in large excess in the sample, most commercial instruments are equipped with a low mass ion gate. Low mass matrix ions are deflected from the detector or the detector is turned on immediately after these low mass ions reach the detector.

The choice among TOF mass analyzers, linear versus reflectron, ultimately depends on the types of analytes to be characterized, and on the available budget. Without question, re-TOF mass analyzers offer higher performance (resolution, mass accuracy) when analyzing lower molecular weight compounds such as peptides, lipids, simple carbohydrates, and oligonucleotides. While in some cases the use of a re-TOF mass analyzer may result in a loss of sensitivity, as the ions must travel through an electrostatic mirror for refocusing, the gains in mass accuracy and resolution usually more than compensate for any sensitivity losses. L-TOF mass analyzers are more effective when high molecular weight ($M_r > 10\text{--}20\text{ kDa}$) are the primary focus of analysis. Examples include intact proteins, glycoproteins, nucleic acids, and polymer complexes.

In addition to traditional TOF mass analyzers, a number of hybrid systems can be used with a MALDI ion source. Hybrid systems tend to be most useful if one needs to obtain structural information on the MALDI-generated ions via collision-induced dissociation (CID) methods. The most common hybrid systems are the tandem time-of-flight (TOF-TOF) and quadrupole time-of-flight (Q-TOF) configurations. The TOF-TOF configuration enables structural studies of MALDI-generated ions at high collision energies. Ion formation occurs under vacuum, similar to standard MALDI-TOF configurations. In contrast, most Q-TOF instruments with a MALDI ion source form ions at atmospheric (or somewhat lower) pressures and focus those ions into the mass analyzer through a quadrupole mass analyzer. In addition to the differences arising by forming ions at atmospheric pressure [28], Q-TOF instruments also have limitations on the mass range that can be analyzed. These differences arise due to the focusing properties of the quadrupole. However, like TOF-TOF systems, the Q-TOF

configuration does enable structural studies of MALDI-generated ions in a low energy quadrupole (or similar) collision cell.

5.3.2 MALDI Matrix Properties and Preparations

5.3.2.1 Matrix Properties. The MALDI technique involves the process of desorption, dissociation, and ionization of the analyte and the matrix under high laser energy. The essence of MALDI-MS is the matrix. Generally, analyte compounds are embedded in a surplus of matrix (ca. 1000-fold molar excess) and are codesorbed on laser excitation. The general features of effective MALDI matrices are already known: they must dissolve (liquid matrix) or cocrystallize (solid matrix) with the sample, strongly absorb the laser light, remain in the condensed phase under high vacuum conditions, stifle both chemical and thermal degradation of the sample, and promote the ionization of the sample via any of a number of mechanisms [7,38–44]. More explicitly, MALDI matrices must have the following properties:

1. **Solubility**, this condition can be expanded to include any solvent system in which the analyte of interest will codissolve with the matrix.
2. **Absorptivity**, which allows the energy to be deposited in the matrix, not the analyte. In UV-MALDI, the matrix is typically an organic compound that has a relatively high molar absorptivity (ϵ_λ) at the wavelength of the laser, and whose structure is based on an aromatic core (a chromophore) suitably functionalized to achieve the desired properties. In the case of IR-MALDI, fewer restrictions apply because wavelengths around 3 μm are effectively absorbed by O–H and N–H stretch vibrations, while wavelengths around 10 μm cause excitation of C–O stretch and O–H bending vibrations. Therefore, nonaromatic compounds can perform well as matrices in IR-MALDI.
3. **Reactivity**, the matrix itself is chemically inert toward the analyte. Matrices that covalently modify analytes cannot be used. A matrix can serve as a protonating or deprotonating agent or as electron-donating or electron-accepting agent.
4. **Volatility**, the matrix should have a sufficiently low vapor pressure to minimize volatilization in the ion source vacuum, yet should sublime relatively easily.
5. **Desorption**, the matrix should facilitate codesorption of the analyte on laser irradiation.

5.3.2.2 Matrix Preparations. Sample preparation/handling is often considered the most important step in MALDI-MS. The quality of the preparation has a direct impact on the quality of the analytical results. Different types of sample preparations are available for various types of analytes and purposes [45,46]. Moreover, most instrument vendors now provide premade MALDI sample targets to reduce both the labor involved in sample preparation and to increase the reproducibility of analysis. Despite these advances, the techniques involved in matrix preparation are worth reviewing. Thus, here we present a brief overview of the three major sample preparation categories: solid matrix, liquid matrix, and special preparations. The interested reader is referred to the following expanded discussion of MALDI matrix preparations (both historical and modern) for more details [47].

5.3.2.2.1 Solid Matrices. The oldest and original sample preparation method introduced in 1988 by Hillenkamp and Karas [9], which has remained, with minor modifications, in place for nearly two decades is the *dried-droplet method*. The approach is simple—a freshly prepared saturated solution of matrix compound is mixed with analyte solution and dried at ambient temperature—but aggregation of higher amounts of analyte/matrix crystals in a ring around the edge of the drop yield inhomogeneous and irregularly distributed crystals on the MALDI target. This inhomogeneity requires the search for “hot” spots to generate good quality spectra [48–50].

Various methods were subsequently developed in attempts to reduce the preparation inhomogeneity. The *crushed crystal* [51], *fast evaporation* [52], *overlayer* [49] and *sandwich* [45,53] methods are the more common examples. Among these, the two-layer (*overlayer*, *sandwich*) approaches wherein the matrix is first spotted on the sample target followed by the analyte and additional matrix or analyte-matrix mixture are most commonly used for solid matrix preparations. These approaches provide high detection sensitivity and excellent spot-to-spot reproducibility, which are mainly due to the increase of the matrix-to-analyte ratio and improved isolation between analyte molecules as a result of analyte/matrix deposition features.

As an alternative approach for reducing analyte/matrix inhomogeneity, the *electrospray* technique was investigated. In the electrospray technique, the sample-analyte mixture is electrosprayed from a high voltage (3–5 kV) stainless steel capillary onto a grounded metal sample plate, mounted 0.5–3 cm away from the tip of the capillary (Fig. 5.3) [54,55]. It creates homogeneous layers of equally sized microcrystals, wherein the analytes are evenly distributed. Later, Caprioli [56] used this sample preparation technique for MALDI imaging of tissue samples, and Clench [57] used it to spray matrix-only solutions on thin layer chromatography plates.

Copyright John Wiley & Sons Limited.

5.3.2.2.2 Liquid Matrices. Owing to difficulties in preparing homogeneous samples using the solid matrix techniques, alternatives based on the use of liquid matrices have also been investigated. Historically, the first technique investigated was the *chemical-doped* liquid technique of Tanaka and coworkers. That approach was subsequently modified by adding an appropriate solubilizing reagent to promote the dissolution of the matrix materials into the liquid support. Selection of the solubilizing reagent is empirically related to an acid–base relationship. This technique has wider scope and can convert most of the solid matrices to the corresponding solution forms to suit different classes of analytes [58].

The more straightforward *chemical liquid* technique simply involves dripping 0.5 μL of liquid matrix (a molar ratio of chemical liquids) onto a 1-mm² area of fibrous paper (Kimwipe™) followed by 0.5 μL of the sample solution. The paper is attached to the sample holder with double-sided sticky tape [59]. In the case of two-phase matrices, fine metal powder or graphite particles are suspended on a low volatility solvent, where the fine particles absorb most of the energy from the laser beam and the liquid molecules provide the charge for ionization. The analyte is mixed with the matrix suspension. After solvent evaporation, the remaining paste on the sample holder is introduced into the ion source [15,60,61]. Other successful chemical liquid approaches involve the addition of solvents that promote ionization or reduce adduct peak formation during MALDI-MS analysis [62].

5.3.2.2.3 Special Preparations. For insoluble samples, it is almost impossible to embed them in a matrix environment by any of the traditional methods. It has been found, however, that by pressing a mixture of finely ground sample and analyte, it is possible to obtain MALDI data from insoluble compounds, for example, insoluble or high molecular weight synthetic polymers. A thick sample is produced by this method, resulting in long-lived samples that yield signals for thousands of laser shots impinging on one location [63].

Among the most unique early developments in MALDI-MS sample preparation was the discovery that solid supports could function as a matrix. Best known is the use of porous Si as a sample support, without the need for any other matrix (desorption/ionization on silicon or DIOS). The concept of an “active” MALDI support is very promising for practical applications, but is not without limitations including a limited mass range, poor reproducibility of the fabrication process, and effect of surface contamination from earlier experiments [64].

5.4 ANALYTE/MATRIX COMBINATIONS OF PHARMACEUTICAL INTEREST

5.4.1 Peptides and Proteins

MALDI-MS owes much of its popularity to its usefulness as an analytical tool for the characterization of peptides and proteins. While an extremely large number of matrix candidates have been investigated for their applicability in peptide and protein analysis, a relatively small group has proved reliable over the past 15+ years. The members of this small group include 2,5-dihydroxybenzoic acid (2,5-DHB) [65], α -cyanohydroxycinnamic acid (CHCA or HCCA) and sinapinic acid (SA)

[66–68]. In addition to these more general purpose matrices, other matrices such as 1,5-diaminonaphthalene (DAN) have found favor in specific applications involving peptides and proteins.

Arguably, the most effective class of matrices for peptide and protein analysis is the class derived from cinnamic acid [66–68]. The most effective of these derivatives are 3,5-dimethoxy-4-hydroxycinnamic acid (SA) and CHCA or HCCA. SA can selectively ionize proteins in the presence of high concentrations of contaminating materials, such as lipids, carbohydrates, and salts. It is relatively nonselective in its behavior toward proteins of significantly different primary structures and modifications (such as phosphorylation and glycosylation). The general affinity of this matrix for proteins, coupled with its ability to tolerate high concentrations of various contaminants (buffering agents, acidification agents, and denaturing agents) allows the application of MS to mixtures of crude biological extracts, including egg white, human blood cell lysates, *Escherichia coli* cell lysates, crude seed extracts, enzyme digest mixtures, and commercial preparations of proteins containing many impurity proteins and peptides. CHCA was found to be a highly effective and efficient matrix for peptides and glycopeptides in the molecular mass range 500–5000. The MALDI mass spectra of proteins obtained from CHCA showed an increased tendency for multiple protonation compared with other widely used matrices.

SA does have two undesirable properties: (i) the formation of an adduct of a photodehydration product of SA with proteins, having a mass 206 Da higher than the protonated protein and (ii) the production of an intense background of ions below m/z 1000, limiting the utility of the technique for the measurement of low mass peptides. With CHCA, certain analytes have been found to undergo fragmentation during MALDI to a degree that complicated their analysis [69]. The excessive fragmentation occurred usually as a post-source-phenomenon; however, in-source fragmentation was also observed.

With the advent of improved mass analyzers, recently there has been significant interest in using MALDI-MS for “top-down” sequencing of biomolecules. In MALDI-TOF-MS, this sequencing approach can be enabled through matrix-driven fragmentation of the biomolecule, either during the desorption/ionization step (in-source) or from metastable fragmentation (post-source). While the matrices described above have been used for in-source decay (ISD) and post-source decay (PSD) sequencing of proteins, DAN [70] has been shown to yield preferred ISD fragmentation from proteins [71].

5.4.2 Glycopeptides and Glycoproteins

Glycopeptides and glycoproteins contain free amino groups that can be protonated efficiently and they exhibit frequently more abundant mass spectral ions than saccharides that are ionized by sodium addition. The ratio of the protonated to sodium adduct for glycopeptides depends on the percent of peptides in the molecule [72]. 2,5-DHB was found to be a preferred matrix for glycopeptides and glycoproteins compared to CHCA and SA by the dried-droplet sample preparation technique, although CHCA with the sandwich sample preparation technique can yield better results for the analysis of glycopeptides [45]. 2,6-Dihydroxyacetophenone (DHAP) containing diammonium hydrogen citrate (DAHC) exhibited superior spectra of sialylated glycopeptides with

better resolution and less fragmentation compared to conventional matrices [73]. Protonated molecular ions were the prominent products and minimal cationic adducts were present during analysis.

5.4.3 Carbohydrates

MALDI-MS is a particularly valuable analysis tool for carbohydrates because it enables underivatized, as well as derivatized, compounds to be examined. MALDI has been applied to the analysis of carbohydrates since the earliest reports of this technique [48]. 2,5-DHB is one of the most successful matrices for carbohydrate analysis. Additives may affect crystallization, embedding the analyte more homogeneously [74]. Using 2-hydroxy-5-methoxybenzoic acid as a comatrix in the 10% range with 2,5-DHB, producing a mixture known as “super-DHB,” resulted in improved ion yields and a two- to threefold increase of signal-to-noise ratio for the analysis of a dextran standard (Dextran 1000) presumably through a disordering in the 2,5-DHB crystal lattice allowing for “softer” desorption [75]. A mixture of 2,5-DHB and 1-hydroxy isoquinoline (HIQ) in a weight ratio of 3:1 was best suited for the analysis of β -cyclodextrin, maltoheptaose, sucrose octaacetate, chitotetraose, and raffinose-5-hydrate, providing enhanced molecular ion abundances, mass resolution, and suppression of unwanted matrix peaks [74].

Acidic oligosaccharides are more difficult to analyze using conventional matrices. 6-aza-2-thiothymine (ATT) and 2,4,6-trihydroxyacetophenone (THAP) were found to be particularly useful for acidic oligosaccharides, with THAP preferred because it gave less fragmentation [76]. In addition, THAP offered improved sensitivity for detection of acidic glycopeptides over CHCA. Among the different substituted acetophenones, 2,5-DHAP produced relatively strong signals from neutral carbohydrates in positive ion mode, which was comparable to 2,5-DHB [72]. Esculetin (6,7-dihydroxycoumarin) efficiently ionized neutral glycans with better resolution than 2,5-DHB in both MALDI and AP-MALDI [72]. 5-Chloro-2-mercaptobenzothiazole (CMBT), an analog of MBT (2-mercapto-benzothiazole), has been found to be not only effective for the analyses of glycolipids but also superior to conventional matrices for the analysis of some oligosaccharides [77].

5.4.4 Lipids

As lipids are low molecular weight compounds, MALDI analysis can be limited because of matrix background products. Thus, although a significant number of studies have been conducted, by far 2,5-DHB has been found to be the most effective matrix for various types of lipids and phospholipids [78–87].

5.4.5 Glycolipids

Underivatized and permethylated gangliosides from commercial sources and highly purified gangliosides from the human brain containing up to five sialic acid residues have been analyzed by MALDI [88]. A variety of matrix and wavelength combinations were tested in both the positive and negative ion modes. The best results were obtained with the matrices 2,5-DHB, 4-hydrazinobenzoic acid, DAN, and ATT. Negative ion mass spectra of the underivatized gangliosides exhibited spectra of better quality than

the positive ion mass spectra with higher signal-to-noise ratios, improved resolution, reduced fragmentation, and as expected, fewer sodium or potassium adducts.

Sphingolipids and both neutral and acidic glycosphingolipids exhibited good signals in the positive ion mode but with the nature and abundance of the molecular ion and extent of fragmentation strongly dependent on the matrix [87]. 2,5-DHB, CHCA, and esculetin were found to provide the best signals. All of the compounds predominantly gave sodium adduct ions, whereas only sphingosine gave abundant protonated molecules. Fragmentation of the oligosaccharide chain of glycolipids containing HexNAc tended to be more random than that seen when HexNAc was absent, and it provided considerable sequence information.

5.4.6 Nucleic Acids

As with other biomolecule compound classes, a large number of candidate matrices have been investigated for the MALDI-MS analysis of nucleic acids. Over the years, only a handful has found widespread use within the field: picolinic acid (PA), 3-hydroxypicolinic acid (3-HPA), ATT and THAP. The *de facto* standard for small oligonucleotides is THAP, together with di- and triammonium salts of organic or inorganic acids [89]. A mixture of THAP in acetonitrile and aqueous triammonium citrate in a 1:1 molar proportion was found to be a good matrix for the detection of synthetic oligodeoxynucleotide samples [90]. A high proportion of volatile solvent as well as the high salt content ensured fast cocrystallization of the matrix, co-matrix and analyte molecules. ATT, co-crystallized with ammonium citrate, has been shown to be a suitable matrix for the analysis of oligonucleotides and short DNA fragments [91]. The major advantages of ATT over other conventional matrices, e.g., THAP and 3-HPA, were improved resolution and mass accuracy, easy sample preparation, and applicability to crude or partially purified samples.

Although 3,4-diaminobenzophenone (DABP) was originally introduced as a novel matrix for the analysis of peptides and proteins by MALDI-MS, it was also demonstrated to be useful in the analysis of oligonucleotides [92]. Intact oligonucleotide ions with this matrix can be readily produced with lower laser powers, resulting in better detection limits, less fragmentation, and fewer alkali metal ion adducts compared to conventional matrices, for example, 3-HPA and THAP. This matrix alone was particularly useful for the analysis of small oligonucleotides (<30-mers) without any co-matrices. Besides, minimal fragmentation and fewer alkali metal ion adducts were seen even at low concentrations of oligonucleotides. It was also found that samples prepared with DABP are highly homogeneous, which resulted in excellent shot-to-shot reproducibility, better resolution and a higher signal-to-noise ratio.

A unique aspect of MALDI-MS analysis of nucleic acid components is the necessity of a co-matrix to minimize cation adduction and improve oligonucleotide signals. The effect of ammonium salt in the detection of oligonucleotides was systematically investigated using several matrices with ammonium salt additives [93]. The results showed that the presence of ammonium salt in the matrix had a beneficial effect on protonation and deprotonation of oligonucleotides in addition to suppressing alkali-ion adducts. The addition of a co-matrix of sufficiently high proton affinity can serve as a proton sink to reduce oligonucleotide fragmentation in MALDI-MS [94,95]. A direct correlation between the comatrix proton affinity and the oligonucleotide molecular ion stability was found. The polyamine co-matrices—spermine tetrahydrochloride,

spermine, spermidine trihydrochloride, and spermidine, were evaluated for their effectiveness in enhancing the mass spectral quality of oligonucleotides [96,97]. In general, polyamine co-matrices were found to be more effective than monofunctional amines for improved mass spectral data.

5.5 SECOND-GENERATION MALDI APPROACHES

The prior section primarily described the use of solid, UV-absorbing organic compounds as matrices for a variety of biomolecular compound classes. As such, those matrix/analyte combinations arise from the Hillenkamp and Karas approach to MALDI-MS. However, while matrices such as 2,5-DHB, CHCA, DABP, and THAP have proved their utility in numerous MALDI-based analyses and publications, investigations into alternative approaches to MALDI-MS have resulted in a significantly different type of matrix—one that is not a low molecular weight organic salt. Three such second-generation MALDI approaches are briefly described below. Because these approaches are either newer or more broadly applicable than those matrices described above, this section focuses on the initial development of these approaches along with representative examples of how such approaches may be used for future MALDI-based investigations.

5.5.1 DIOS (Desorption/Ionization on Silicon)

Just as the matrix serves to trap analyte molecules and absorb UV radiation, nanoporous materials such as porous silicon were found by Siuzdak and coworkers to be an effective medium for desorbing compounds as well as generating intact ions in the gas phase [64,98–101]. This is due to the ability of its nanometer-sized pores to trap analyte molecules, and to the silicon surface, with its photoactive and photoluminescent characteristics, that effectively absorbs UV light. This approach, DIOS has demonstrated characteristics similar to MALDI in that intact molecules are observed at the femtomole to attomole levels with little or no fragmentation (Fig. 5.4) [64,99]. The structure and physiochemical properties of the porous silicon surfaces are vital for DIOS-MS performance and are controlled by the selection of silicon and the electrochemical etching conditions [100]. DIOS surfaces are produced through a simple galvanostatic etching procedure which yields a UV-absorbing porous silicon exterior with high surface area and thermal insulating properties.

The observation of a variety of intact ions directly desorbed from these surfaces suggests that porous silicon has properties such as high surface area and strong ultraviolet absorption that may enhance pulsed LD and ionization. The energy for analyte release from the surface may be transferred from silicon to the trapped analyte through vibrational pathways, or as a result of the rapid heating of porous silicon, producing hydrogen that releases the analyte, which was defended by a study of Ogata *et al.* [102] on possible changes in the environment of hydrogen in porous silicon with thermal annealing. It has also been noted that porous silicon absorbs hydrocarbons from outside air, or while under vacuum, thus rapid heating/vaporization of trapped hydrocarbon contaminants or solvent molecules may increase the vaporization and ionization of the analyte embedded in the porous silicon. DIOS-MS offers good sensitivity, high

Figure 5.4 Experimental configuration for the DIOS-MS experiments. (a) Four porous silicon plates are placed on a MALDI plate. Each of the porous silicon plates contains photopatterned spots or grids prepared through illumination of *n*-type silicon with a 300-W tungsten filament through a mask and an *f*/50 reducing lens. (b) The silicon-based laser desorption/ionization process, in which the sample is placed on the porous silicon plate and allowed to dry, followed by laser-induced desorption/ionization mass spectrometry. (c) Cross section of porous silicon, and the surface functionalities after hydrosilylation; R represents phenyl or alkyl chains. *Source*: Figure reprinted by permission from Macmillan Publishers Ltd: Nature. “Desorption/ionization mass spectrometry on porous silicon.” Wei J, Buriak J, Siuzdak G. *Nature* 1999;399:243–246. tolerance to contaminants, no matrix interference and more control over biological MS as the surface properties of porous silicon can easily be customized [64].

5.5.2 Carbon Nanotubes

Carbon nanotubes (CNTs), prepared from coal by an arc discharge method, were investigated as the matrix for analyses of small molecules by MALDI-MS [103]. It was observed that the CNT layer on the probe before deposition of the sample solution appears to have web morphology, which was masked by formation of analyte micro-crystals after deposition of the sample solution. However, there is almost no change in configuration and shape for a single piece of CNT before and after the deposition of sample solution on the CNT layer (Fig. 5.5). Nanotubes provide a lower laser power threshold for desorption/ionization and higher detection sensitivity and mass resolution of small molecules than organic matrices. CNTs may greatly simplify sample preparation, eliminate interference of matrix background ions, and improve shot-to-shot reproducibility. A type of polyurethane adhesive, NIPPOLAN-DC 205, was employed to improve the applicability of CNTs as matrices for analyses of low mass weight compounds [104].

A functionalized CNT, CNT 2,5-dihydroxybenzyl hydrazine derivative, was synthesized and used as both a pH adjustable enriching reagent and as a matrix in MALDI-MS analysis of trace peptides [105]. Functionalized CNT provided two-fold advantages

Figure 5.5 (a) Morphology of carbon nanotube layer on probe well before and after dropping sample solution and (b) scanning electron microscopy (SEM) image ($\times 5000$ -fold) of carbon nanotube layer before and after dropping sample solution. (c) and (d) Transmission electron microscopy (TEM) image ($\times 100,000$ -fold) of carbon nanotube layer before and after being deposited by sample solution. *Source:* Figures reproduced with permission from “Carbon nanotubes as assisted matrix for laser desorption/ionization time-of-flight mass spectrometry.” Xu S, Li Y, Zou H, *et al.* *Anal Chem* 2003;75:6191–6195. over pristine CNT. The efficiency of enrichment of trace peptides was greatly enhanced as a result of increased surface area to volume ratio for adsorption in basic conditions. It also provided a convenient method for quick isolation. Compared with CHCA without enrichment, the detection limit for analytes can be enhanced about 10 to 100 times after enrichment by the functionalized CNT.

5.5.3 Room Temperature Ionic Liquid Matrices

Room temperature ionic liquids (RTILs) are salts with melting points close to or below room temperature. They look like a classical liquid but they do not contain any molecules: they are made of ions. Typically, an RTIL consists of nitrogen- or phosphorus-containing organic cations and large organic or inorganic anions [106]. They have good thermal stabilities, remain liquid over a range of 200 to 300°C and

have practically no vapor pressure [107]. They produce homogeneous solutions with great vacuum stabilities and are good solvents for a variety of organic, inorganic, and polymeric substances [108].

It has been demonstrated that ionic liquids and solids make useful MALDI matrices [109–115]. With ionic matrices, it is possible to combine the beneficial qualities of liquid and solid matrices. Ionic liquids produce a much more homogeneous sample solution (as do all liquid matrices), yet they have greater vacuum stability than most solid matrices. In most cases, an ionic matrix that produces greater spectral peak intensities and lower limits of detection than comparable solid matrices can be found. Most ionic liquids readily dissolve biological oligomers, proteins, and polymers. However, ionic liquids can vary tremendously in their ability to promote analyte ionization. Both the cationic and anionic portion of the ionic matrix must be chosen with a consideration for the special requirements of UV-MALDI detection. The ionic matrix must not only have significant absorbance at the desired wavelength but also available protons. Most conventional ionic liquids that lack these properties are ineffective as MALDI matrices (Fig. 5.6).

Zabet-Moghaddam *et al.* [114] characterized five different ionic liquids by laser desorption ionization (LDI) and by MALDI-MS. Signals of both anions and cations of the ionic liquids could be observed both in LDI- and in MALDI-MS without any metal adducts. Low molecular mass compounds and peptides could be analyzed best in the presence of water-immiscible ionic liquids, whereas proteins gave the best results in water-miscible ionic liquids. Optimal analytical conditions depend on the molar ratio of matrix-to-analyte and ionic liquid-to-matrix, although the homogeneity of samples in the presence of ionic liquids was reduced compared with classical MALDI preparations.

Recently, direct tissue profiling of peptides with ionic liquids made of matrix mixtures (CHCA/2-amino-4-methyl-5-nitropyridine (CHCA/2A4M5NP) and CHCA/*N*, *N*-dimethylaniline (CHCA/DANI)) was reported [116]. The ionic matrices were found to have several advantageous features for direct tissue analysis, especially CHCA/aniline as compared to CHCA, 2,5-DHB, and SA. These advantages included improved signal intensity and sensitivity, homogeneous crystallization, the possibility of *in situ* partial fragmentations, a high resistance to laser ablation especially using a high repetition rate laser, and the possibility to analyze compounds in positive and negative modes using the same slice for MALDI-MS high quality imaging.

5.6 USING MALDI-MS FOR STRUCTURAL CHARACTERIZATION OF BIOMOLECULES

Structural characterization of biomolecules or other analytes can be performed using MALDI-MS. MALDI-MS is particularly well suited for the analysis of enzymatic or chemical digestions of larger biomolecules including proteins, nucleic acids, and polysaccharides [117–119]. As with many other categories of MS, gas-phase sequencing of the analyte can be performed in MALDI-TOF-MS. In MALDI-MS, the desorption/ionization step itself is sufficiently energetic to cause fragmentation, and this fragmentation process depends on the chemical behavior of both analyte and matrix, as well as the type of instrumentation utilized. Fragmentation initiated by the desorption/ionization process is a continuous process, which begins immediately as the ions

Figure 5.6 MALDI mass spectra of the three oligonucleotides d(pT)₁₀, d(pC)₁₁, and d(pC)₁₂ in different matrices: (a) 3-HPA-10% ammonium citrate, (b) ionic solid 21, and (c) ionic solid 26. Spectra obtained cumulating 100 UV 237-nm laser shots. For the three experiments, the oligonucleotide-to-matrix molar ratio was 1:500,000 and the laser fluence was the same (attenuation 10). The signal strength is expressed in arbitrary units corresponding to the accumulation of 100 shots on a good spot. The 3-HPA scale (top spectrum) differs eight times from that for the two salts (bottom spectra). *Source:* Figure reproduced with permission from "Ionic matrices for matrix-assisted laser desorption/ionization time-of-flight detection of DNA oligomers." are formed and continues until they are detected. There are essentially four differing time scales for desorption/ionization-induced dissociations in MALDI-TOF-MS: prompt, fast, fast metastable, and metastable.

1. Prompt dissociations occur on a time scale equal to or less than the desorption event.
2. Fast dissociations occur after the desorption event, but before or at the beginning of the acceleration event.
3. Fast metastable decays occur on the time scale of the acceleration event.
4. Metastable decays occur after the acceleration event, during the field-free flight time of the ion.

From these various dissociation pathways, two analytical methods have been developed for the structural characterization of biomolecules: PSD and ISD sequencing techniques.

5.6.1 Post-Source Decay

Many samples undergo metastable decompositions during their travel in the field-free region of a TOF mass spectrometer. This metastable decay process is dependent on many variables but is primarily influenced by the matrix. PSD requires the use of a re-TOF mass spectrometer for the accurate characterization of these metastable ions [120]. By adjusting the retarding voltages on the reflectron ion mirror, the metastable ions can be brought into focus at the detector. PSD is most applicable for the sequence characterization of small to moderate length peptides, and when combined with other enzymatic or chemical digestion approaches, can be used for protein characterization [121,122]. PSD has also been demonstrated for the structural characterization of oligosaccharides (Fig. 5.7), some synthetic polymers, and oligonucleotides [123–125]. The drawbacks of PSD-based methods for structural analysis are the typically longer analysis times (as compared to ISD, below) and the relatively large precursor mass selection window that limits detection or hinders assignment of some fragment ions.

5.6.2 In-Source Decay

ISD was first reported in 1995, where backbone fragmentation of proteins was shown to yield resolvable fragment ions [126]. With the advent of “top-down” methods for biomolecular sequencing, wherein the analyst focuses on obtaining structural information from the intact biomolecule of interest, MALDI-based ISD sequencing has proved both efficient and effective in obtaining wide-sequence coverage from a minimal amount of sample. ISD has proved to be more useful and effective for the structural characterization of a good range of biomolecules, including carbohydrates [127–129] peptides (Fig. 5.8) [130,131] and proteins [132,133]. As mentioned earlier, matrices such as 1,5-DAN promote radical-initiated fragmentation of protein backbones, providing a relatively facile route for high sequence coverage for moderate (up to tens of kilodaltons) proteins [70,71].

Implementation of ISD on modern MALDI-TOF mass spectrometers is routine. Unlike “conventional” MALDI-MS, where one operates at a laser fluence below

Figure 5.7 Negative ion PSD of chloride adducts of 1–6 linked disaccharides. (a) gentiobiose($\text{Glc}\beta 1\text{--}6\text{Glc}$); (b) isomaltose ($\text{Glc}\alpha 1\text{--}6\text{Glc}$); (c) $\text{Gal}\beta 1\text{--}6\text{Gal}$; (d) melibiose ($\text{Gal}\alpha 1\text{--}6\text{Glc}$); and (e) $\text{Man}\alpha 1\text{--}6\text{Man}$. The α -(isomaltose) and β -configuration (gentiobiose) in 1–6 linked glucopyranosyl disaccharides can be readily differentiated by examining whether the relative abundance ratio of m/z 251:281 is larger than unity (β isomer) (Fig. 5.7a) or smaller than unity (α isomer) (Fig. 5.7b). This peak intensity difference is also applicable to other 1–6 linked disaccharides. *Source*: Figure reproduced with permission from Guan B, Cole R.B. MALDI linear-field reflectron TOF post-source decay analysis of underivatized oligosaccharides: determination of glycosidic linkages and anomeric configurations using anion attachment. *J Am Soc Mass Spectrom* 2008;19:1119–1131. © 2008 American Society for Mass Spectrometry.

threshold, to promote ISD one operates at higher laser fluences, which are empirically determined. As fragmentation occurs within the source region of the mass spectrometer, the use of time-lag focusing or DE techniques (described above) are necessary to fully resolve and accurately characterize these fragment ions. Details of the ISD process and its applications in the structural characterization of biomolecules are available in a recent review [134].

5.7 METHODOLOGY AND APPLICATIONS

Molar mass is an intrinsic molecular property, which, when measured with sufficient accuracy, becomes a unique and unusually effective parameter for characterization

Figure 5.8 MALDI orthogonal-TOF mass spectra of (a) fibrinopeptide A (human, MW 1536.57 u) and (b) its (Leu/Ile) 9-substituted isomer recorded at a buffer gas pressure of 1.2 mbar. The small insets show the full mass spectra including the molecular ion regions, the expanded regions at the bottom the m/z range from 670 to 770. Asterisks denote matrix cluster derived ion species. *Source:* Figure reprinted with permission from Soltwisch J, Dreisewerd K. Discrimination of isobaric leucine and isoleucine residues and analysis of post-translational modifications in peptides by MALDI in-source decay mass spectrometry combined with collisional cooling. *Anal Chem* 2010;82:5628–5635. copyright 2010 American Chemical Society.

of chemical compounds. MALDI-MS experiments include conventional determination of molecular weights, structural characterization via analysis of sequence-informative product ions, and, in some cases, quantitative determination of an analyte from a sample. The level of mass accuracy and the overall usefulness of molecular weight determination will depend on the capabilities of the mass analyzer and the quality of the mass spectral results. Depending on the instrument configuration and type of sample, mass measurement accuracies are on the order of 0.01–1% with sensitivities at the pmol–subfmol level. One clear advantage of MALDI-MS over spray-based methods which generate multiply charged ions (such as ESI-MS) is the tendency of MALDI-MS to yield mass spectra characterized by singly charged ions. Mass assignments are readily made, which can often improve compound identification or allow for the analysis of simple mixtures of analytes without requiring prior separation of the mixture.

MALDI-MS has been used in a variety of applications. One of the more recent and promising applications of MALDI-MS in the field of drug metabolism is MALDI-based mass spectrometry imaging (MSI). MALDI-MSI is the subject of the chapter titled *Gas-Phase Ion Mobility-Mass Spectrometry (IM-MS) and Tandem IM-MS/MS Strategies for Metabolism Studies and Metabolomics* in this volume; thus, it is not be discussed here. A significant number of timely reviews on other applications of MALDI-MS in the pharmaceutical field have been published [17,135–146], and the interested reader is referred there for more comprehensive coverage of these applications. Below, several applications of particular importance to the pharmaceutical industry are described.

5.7.1 Bacterial Identification

One application where the characteristics of MALDI-MS provide clear advantages over ESI-based methods is in the field of bacterial identification. Lay and coworkers first demonstrated the direct identification of bacterial strains by MALDI-TOF-MS in 1996 [147]. Since then, numerous publications and dedicated MALDI-based systems have arisen for this specific application [142]. Bacterial identification via MALDI-MS is possible because it has been shown that, more often than not, each bacterial species generates a unique MALDI mass spectrum fingerprint, which can be used for identification (Fig. 5.9). When sample handling and preparation is standardized, then such fingerprints can be queried against a database of organism MALDI-MS spectra allowing for routine and rapid identification. While analytical challenges remain present when attempting to differentiate pathogenic from nonpathogenic strains of certain bacteria, this MALDI-based approach cannot be duplicated by any ESI-based method in terms of speed, simplicity, and sensitivity. Of particular interest at the present time is the ability to use such identifications to identify infection loads within patients via identification of bacteria in serum and plasma [140]. While there are obvious clinical implications to such studies, this approach can also prove useful in studying new drug efficacy and potency in clearing infections. Further, when combined with recent advances in MALDI-MS analysis of small molecules (described below), MALDI-MS can be considered as a complementary workhorse for the analytical laboratory supporting the development of new drug entities (NDEs) as well as a useful tool during clinical studies.

5.7.2 Small Molecule Analysis

While MALDI-MS has traditionally been overlooked as an analytical method for the identification and quantification of small molecules ($M_r < 750$ Da), several research groups have been developing new techniques and modifications to conventional MALDI-MS that would enable its use in this field. As noted earlier in this chapter, one of the historical limitations of MALDI-MS is that the requirement of a matrix tends to result in a high background below $m/z 1000$ because of matrix-related ions including matrix cluster ions and matrix adduct ions. Further, sample preparation challenges can lead to inhomogeneous sample/matrix mixtures, which hinders accurate and precise quantitative analysis by MALDI-MS.

However, the advantages of MALDI-MS (speed, simplicity, sensitivity, and minimal sample consumption) provide a clear motivation to seek out alternative approaches in the type of matrices used as well as sample preparation that would enable the use of MALDI-MS for high throughput analysis of small molecules. Although the various approaches investigated are too numerous to discuss here, the most promising include the use of high molecular weight matrices and automation of sample preparation techniques [139]. Because the high background in the low mass region of a MALDI mass spectrum arises from matrix-related ions [148], investigations into the use of matrices whose molecular mass is above 1000 Da were pursued with reasonable success [149,150]. While porphyrins have been a popular choice for high molecular weight matrices, certain polymers and pure carbon materials (such as CNTs described earlier) also show promise. It deserves mention here that matrix-free MALDI preparations, such as the DIOS approach that was discussed earlier, are also suitable techniques for characterizing small molecules by MALDI.

In addition to the numerous refinements in sample preparation that were covered earlier in this chapter, approaches that automate sample preparation using robotically controlled electrospray-like deposition and approaches that can (pre-)concentrate the sample or sample/matrix solution are useful when attempting to perform quantitative analysis of small molecules by MALDI-MS. Among the latter, the use of hydrophobic sample targets [151] has proved to be both effective and easily implemented, either commercially (AnchorChip™ technology) or by simple modification of existing sample target plates [152].

5.7.3 Applications in Drug Delivery

The final application highlighted here, where MALDI-MS demonstrates clear utility and advantages over ESI-based methods, is the characterization of drug delivery systems. In the majority of the instances where MALDI-MS has been used, the drug delivery vehicle has been a high(er) molecular weight polymer. A detailed review of this application area has recently been published [138], but from the MS perspective the advantages of MALDI-MS for polymer analysis are several. First, because—by definition—polymeric systems contain multiple components, the use of an ionization method that can handle such “mixtures” without necessitating on-line separation is a clear advantage in terms of analysis simplicity and speed. Further, the analysis of polymers by MALDI-MS has a long and rich history [153], which allows investigators interested in biocompatible polymers easy entry into the field as standard matrix/analyte compositions and preparations have already been established. Another advantage for

Figure 5.10 Positive ion MALDI linear TOF-MS of interferon $\alpha 2a$ (IFN $\alpha 2a$) monoPEGylated with a 40-kDa branched polyethylene glycol (PEGrIFN): (a) with a standard secondary electron multiplier detector and (b) with a high mass detector. *Source:* Figure reprinted with permission from Seyfried B, Siekmann J, Belgacem O, *et al.* MALDI linear TOF mass spectrometry of PEGylated (glyco)proteins. *J Mass Spectrom* 2010;45:612–617. copyright 2010 John Wiley & Sons.

MALDI-MS, especially when used with TOF mass analyzers, is the ability to characterize high molecular weight distributions at low charge state (high m/z values), thereby reducing the need for spectral deconvolution prior to data interpretation (Fig. 5.10). As improvements in MALDI-based approaches for quantitative analysis increase, the use of this analytical method to identify stoichiometries in polyplexes (drug–polymer noncovalent complexes) should not be far behind.

5.8 SUMMARY

MALDI-MS has become a very powerful tool for the analytical characterization of a wide variety of samples. MALDI-MS owes its beginnings to early work performed on LD/ionization MS. However, it was not until the introduction of the strongly UV-absorbing matrix that this technique became a widely acclaimed and accepted instrumental method for chemical characterization. MALDI-MS was independently reported by Hillenkamp and coworkers [13] and Tanaka and coworkers [8]. Hillenkamp and coworkers described the use of a solid crystalline matrix (nicotinic acid), which has become the standard approach to MALDI-MS. Interestingly, both groups reported

initial success with liquid matrices, an approach that has seen a recent resurgence [58,114].

MALDI-MS is, without question, one of the developments in ionization methods for MS (the other being ESI) that have significantly advanced the applications of MS to high molecular weight, nonvolatile, and thermally labile samples. MALDI-MS is particularly well suited for the characterization of polar compounds, a trait that is, more than any other, responsible for the success of this ionization technique.

Conceptually, sample analysis using MALDI-MS is a relatively straightforward procedure. As described in detail earlier, the analyte of interest is mixed with an appropriate matrix, spotted on a sample plate and analyzed. The analyte is detected in the mass spectrum predominantly as a singly charged ion, simplifying its identification. MALDI-MS is a simple, versatile, and powerful analytical tool that is now found in all types of research laboratories. In fact, the performance characteristics of MALDI-MS have made it an almost indispensable method for the modern bioanalytical laboratory, and, as illustrated in the three representative applications in this chapter, MALDI-MS should be considered a necessary and advantageous analytical tool in pharmaceutical research.

6.1 SUMMARY

Mass spectrometers based on ion separation using electrodynamic quadrupolar fields have been dominant in the evolution of the field of mass spectrometry. This chapter discusses triple quadrupole mass spectrometers and quadrupole ion trap mass spectrometers, two of the most important and commercially successful instruments in the history of mass spectrometry. An overview of the principles of operation is discussed in terms of the Mathieu stability diagram, a well-known graphical representation to determine whether ions will have stable or unstable trajectories in a radio frequency (RF) electric field. A brief introduction of tandem mass spectrometry (MS/MS) is also presented.

After the general introduction, each type of instrument is discussed individually. It should be noted that while both types of instruments are based on the same theory of ion motion in electrodynamic fields, there are very important differences in the way experiments are implemented. This is in large part because the triple quadrupole mass spectrometer is the so-called beam instrument where the different stages of an experiment are performed “in space” as the ions travel from the ion source to the detector. Conversely, quadrupole ion traps are “trapping” instruments and the stages of the experiment are performed sequentially “in time,” with the ions being manipulated in the electric field.

A brief historical background is provided for each type of instrument, and then the method of operation is covered with an emphasis on the MS/MS capabilities. For the triple quadrupole mass spectrometer, its key MS/MS feature is the variety of MS/MS

modes in which it can be operated: product ion scan, parent ion scan, neutral loss scan, and single and multiple reaction monitoring.

The discussion of quadrupole ion traps first covers how ions are manipulated in the device. The ability to manipulate ions (“ion taming”) is one factor that makes the quadrupole ion trap a very useful instrument. The ion manipulation is critical in MS/MS operation. Differences between the operation of 2D and 3D instruments are also covered. Finally, there is an overview of the wide array of methods to perform MS/MS experiments: collisional activation using resonance or nonresonance techniques, infrared multiphoton dissociation (IRMPD), and gas-phase chemical reactions, namely, ion–molecule and ion–ion reactions.

6.2 INTRODUCTION

There are two types of quadrupole mass analyzers that use rf electric fields to confine ions in two or three dimensions: the beam-type quadrupole mass filter and the trapping quadrupole ion trap mass spectrometer. The quadrupole mass filter and two-dimensional (2D) quadrupole ion trap are physically composed of four parallel rods, which are typically hyperbolic (ideal) or round [1]. While the quadrupole name is widely applied to rods themselves, it is the electric fields produced between the electrodes (shown in Fig. 6.1) that are of analytical value, hence the three-dimensional (3D) ion traps consisting of three electrodes are referred to as *quadrupole ion traps*, although sometime also referred to as *Paul traps*, after the inventor Wolfgang Paul [1]. Because

Figure 6.1 Axial view of a quadrupole mass filter rod assembled with an equipotential electric field plot. In an ideal system, the electric field is quadratic. The plot for a three-dimensional quadrupole ion trap would look very similar, with differences mainly in electrode spacing.

the electric field is created with an rf potential, the quadrupole field is dynamic. At any given point in time, the ions experience a field that forces them toward the center of the device in one dimension (trapping) and a corresponding field that forces them away from the center in the other dimension (repelling). As the phase of the rf voltage changes, the dimension in which the ions are trapped and the dimension in which they are repelled alternate back and forth at the frequency of the applied rf voltage. If this frequency is in the appropriate range, typically in the hundreds of kilohertz to a couple of megahertz, the ions have a stable trajectory that periodically goes through the center of the device, or as is commonly stated, the ions are trapped.

Of the mass spectrometers most commonly used today, those containing quadrupole mass filters are the oldest and most mature. The most common configurations for mass spectrometers using the quadrupole mass filter are the single quadrupole instrument (typically coupled to some form of chromatography), the triple quadrupole instrument (which for current instruments may instead consists of two quadrupoles and a higher order multipole), or a quadrupole used in conjunction with another type of mass analyzer to create a hybrid instrument. By grouping quadrupoles in tandem or coupling with another mass analyzer MS/MS experiments can be performed. Most of the modern day MS/MS instruments using quadrupole fields found their origin in work 25–30 years ago.

6.2.1 General Theory of Operation

The physics of ion motion in a quadrupolar field is the same whether the ions are analyzed by a single quadrupole mass filter or multiple quadrupole mass filters in series. In addition, the principles of a quadrupole mass filter can be modified slightly to produce 2D and 3D ion traps. All quadrupoles require the use of rf waveforms to confine ions to stable trajectories allowing them to be either transmitted from entrance to exit or trapped within the volume of the device. At a given value of rf voltage, a dc voltage can be added to define the range of ion mass-to-charge ratios that will have stable trajectories. In the case of beam-type quadrupole mass filters, rf and dc voltages of the same phase or polarity are applied to pairs of rods directly opposite each other, with adjacent rods being 180° out of phase for rf voltages and of opposite polarity for dc potentials. The stability of ions in a linear quadrupole is achieved when the ion motion in the radial dimensions of the quadrupole never exceeds the inscribed radius, r_0 , of the rods. The motion of the ions can be described by a second-order differential equation. The details of the equation of motion are not critical to the general understanding of how a quadrupole works; it is sufficient to know that a general solution to the problem can be derived from the Mathieu equations developed in the late 1800s [2]. Ion trajectories fall into one of the two following classes: stable, where the motion periodically passes back through the origin, and unstable, where the motion increases to infinity. Determination of whether an ion has a stable trajectory or unstable trajectory depends on what is known as the Mathieu parameters q_u and a_u (Eqs. 6.1 and 6.2).

$$q_u = \frac{4eV}{m\Omega^2 r_0^2} \quad (6.1)$$

$$a_u = \frac{8eU}{m\Omega^2 r_0^2} \quad (6.2)$$

In these equations, m is the mass of the ion, Ω is the frequency of the rf voltage applied to the rods (which is called hereafter as the *drive voltage* to differentiate it from other rf voltages that can be applied to manipulate ions), r_0 is the radius of the circle inscribed in the rod assembly, V is the amplitude (0-to-peak) of the rf drive voltage, U is the amplitude of the dc voltage, e is the charge, and u is the dimension to which the equation applies (x or y —the z -dimension is along the length of the rods). The set of solutions calculated by the Mathieu equation for stable trajectories of ions is often plotted in what is referred to as the *Mathieu stability diagram*. In Fig. 6.2, the stability diagram for a quadrupole mass filter is plotted. Ions having a and q values within the dashed lines have stable trajectories and those outside the dashed lines are unstable. It should be emphasized that this treatment does not provide information about the actual physical x - and y -positions of a given ion, only that the values of x and y are always less than the distance from the origin to the rods (stable) or whether the ion trajectory will at some point in time exceed the radius of the device in either the x - or y -dimension.

When a quadrupole mass filter operates with just rf drive voltages applied to the rods ($U = 0$), it behaves as a high pass filter, allowing the transmission of all ions with mass-to-charge ratios greater than the low mass cutoff i.e. those mass-to-charge ratios

Figure 6.2 The Mathieu stability diagram for a quadrupole mass filter and a 2D quadrupole ion trap. The stability region is symmetrical about the q -axis. In this plot, the a and q values are shown for ions of different mass-to-charge ratios when there is no mass resolving dc voltage applied (rf-only mode). Mass-to-charge ratios are represented by the diameter of the dots.

that have a q_u value less than 0.908 (Fig. 6.2). When operated in such a manner, the quadrupole mass filter functions as an ion guide. This mode of operation has played a major role in the development of quadrupole systems for MS/MS.

Mass analysis in quadrupole mass filters is accomplished by the application of both rf and dc voltages to the rod sets. For a given value of V and U , each mass-to-charge value will lie along a “scan line.” The ratio of the rf and dc voltages is selected such that the line passes through a small area at the apex of the stability region (Fig. 6.3). In this case, ideally ions of only a single mass-to-charge value will have stable trajectories in the device. As the rf and dc amplitudes are increased, keeping the ratio constant, successively larger mass-to-charge ratios are stable and will pass through the device to the detector.

For the 3D quadrupole ion trap, the same Mathieu equation applies, but in three dimensions. The x - and y -dimensions, which are the plane of the ring electrode, are combined in polar coordinates to give a radial dimension (r), and now, there is also an rf field in the z -dimension. To meet the conditions of the Laplace equation, there is an asymmetry between the r - and z -dimensions ($r^2 = 2z^2$), so the Mathieu

Figure 6.3 The Mathieu stability diagram for the operation of a quadrupole mass filter. The ratio of the rf to dc voltage determines the slope of the line on which lie the ions' a and q values. The values are selected such that only one mass-to-charge ratio lies within the stability region. That mass-to-charge ratio will be transmitted through the quadrupole to the detector. All other ions have a and q values that lie outside the stability diagram resulting in unstable trajectories through the mass filter.

Figure 6.4 The Mathieu stability diagram for a three-dimensional quadrupole ion trap. The stability region is not symmetrical, but the intersection with the q -axis for $a = 0$ (rf-only mode) is still $q = 0.908$.

stability diagram for the three-dimensional ion trap (Fig. 6.4) is not symmetric like the quadrupole mass filter. The a_u and q_u equations are shown below.

$$a_z = -2a_r = \frac{16eU}{m\Omega^2 r_0^2} \quad (6.3)$$

$$q_z = -2q_r = \frac{8eV}{m\Omega^2 r_0^2} \quad (6.4)$$

It is important to note that while stable ions pass through the quadrupole mass filter and hit a detector, stable ions in a 3D quadrupole ion trap remain in the device and thus they need to be further manipulated to be detected (see later discussion). This added operational complexity hindered the development into a mass spectrometer of the 3D quadrupole ion trap for several decades after the quadrupole mass filter was commercialized.

A key feature of quadrupole-based instruments is the ease with which they can be interfaced to chromatography methods. Gas chromatography/MS and liquid chromatography/MS using single quadrupole devices are routine methods. However, the feature that is probably most important in the success of quadrupole-based devices is the ability to perform MS/MS [3]. In fact, the triple quadrupole was developed expressly for MS/MS. The MS/MS experiment can be divided into three distinct steps.

In the first step, an ion formed in the ion source is isolated in the first stage of MS. This ion, called the *parent ion* or *precursor ion*, is then reacted in some manner (step two). The ions thus produced from the reaction of the parent ions, called *product ions*, are analyzed in the second stage of MS (step three). This is often referred to as taking the mass spectrum of an ion in a mass spectrum. It also has analogies to chromatography/mass spectrometry experiments where the chromatography separation is replaced by the first stage of MS.

The reaction of the parent ions to generate product ions is a key component to the MS/MS experiment. Before quadrupole-based instruments, collision-induced dissociation [CID, also called *collision-activated dissociation (CAD)*] was the only reaction used. The development of quadrupole-based instruments expanded the types of reactions that could be used for MS/MS. Current reactions used include ion–molecule reactions, ion–ion reactions, ion–electron reactions, and photodissociation. However, CID is still by far the most widely used reaction.

The CID reaction involves colliding the parent ion with a target (collision) gas. To avoid chemically reactive collisions, a nonreactive gas is typically used, such as He, Ar, or N₂. The collision between the parent ion and the target can convert kinetic energy of the parent ion into internal energy of the parent ion, internal energy of the target gas, or kinetic energy of the target gas. Only the first process is useful in the MS/MS experiment. If the parent ion acquires sufficient internal energy, it will dissociate to give product ions that can be used to identify the parent ion structure. Conversion of the parent ion's kinetic energy to target gas internal energy can be minimized using a monoatomic target gas to eliminate the possibility of vibrational excitation of the target gas. N₂ is often used as a compromise target gas because of its low cost, and while not monoatomic, it has a limited number of degrees of freedom.

While the dynamics and kinematics of the ion-neutral collisions are quite complex, at a basic level, fragmentation of the parent ion is dependent on the amount of ion kinetic energy that can be converted into ion internal energy. The maximum amount of internal energy that can be obtained in a collision with a target gas is the center-of-mass collision energy (Eq. 6.5)

$$E_{\text{com}} = E_{\text{lab}} \left(\frac{m_t}{m_t + m_i} \right) \quad (6.5)$$

where E_{com} is the center-of-mass collision energy, E_{lab} is the parent ion laboratory kinetic energy, m_t is the mass of the target gas, and m_i is the mass of the parent ion. Given that the most commonly used collision gases have masses from 4 to 40 Da and parent ions have masses in the hundreds of daltons, only a small fraction of the ion kinetic energy can be converted to internal energy, even in the best case when all the center-of-mass collision energy is converted to internal energy. For quadrupole-based MS/MS instruments, the ion kinetic energy usually is in the range of 5–20 eV. Thus, multiple collisions are necessary to produce dissociation.

Both triple quadrupole mass spectrometers and ion trap mass spectrometers are powerful MS/MS instruments, but there are very substantial differences in their capabilities and methods of operation. The rest of this chapter is divided into two major sections, one dealing with the quadrupole mass filters in MS/MS and the other, quadrupole ion traps, both 3D (the original quadrupole ion trap) and 2D (a common component of mass spectrometers at present).

6.3 TRIPLE QUADRUPOLE MASS SPECTROMETERS

6.3.1 Origin

The linear quadrupole mass analyzer was first described in the scientific literature in 1958 [4] and has been used since as a mass filter, ion guide, and ion trap. The first commercial single quadrupole mass analyzer instrument, used as a residual gas analyzer, became available in 1961 [5]. In 1974, the first arrangement to be used for MS/MS, three quadrupoles in series, was published [6]. This instrument used a mass-analyzing quadrupole (Q1) to isolate parent ions for transmission into the second quadrupole operated as an rf-only ion guide. As these ions passed through the second quadrupole (q2), they were photodissociated. The products of the photodissociation and any remaining parent ions were then mass analyzed with the third mass quadrupole (Q3). It was the work of Yost and Enke in 1977 that produced the basic design for all the so-called triple quadrupole instruments to come. The key aspect of the QqQ geometry is the middle quadrupole (q) being operated in the rf-only mode and with a collision gas introduced to effect CID [7]. From an instrumental perspective, CID is much simpler to implement than photodissociation and is also much more efficient in a beam-type experiment, so the development of CID in a quadrupole ion guide made possible a commercially viable instrument.

A generic schematic of a triple quadrupole is shown in Fig. 6.5. One of the attractive features of triple quadrupoles is the simplicity of operation. The mass-analyzing quadrupoles (Q1 and Q3) are operated as shown in Fig. 6.3; that is, a scan line determined by the ratio of the rf and dc voltages intersects the apex of the stability diagram and ions of only a single mass-to-charge ratio are transmitted through the quadrupole. To obtain a mass spectrum, Q1 can be mass-selectively scanned while q2 and Q3 are operated in rf-only mode, producing a mass spectrum identical to the operation of a single quadrupole analyzer. Conversely, the same can be achieved by operating Q1 and q2 in the rf-only mode while mass scanning Q3 to produce a single stage of mass analysis.

6.3.2 Tandem Mass Spectrometry

Each stage of the MS/MS experiment in a triple quadrupole is performed in a different quadrupole, and thus, the experiment is sometimes referred to as *tandem-in-space*. The quadrupole in which the dissociation is effected (q2) functions as an ion guide

Figure 6.5 A schematic of a triple quadrupole mass spectrometer. Q1 and Q3 can be operated in either a mass filter mode (Fig. 6.3) or the rf-only mode (Fig. 6.2). q2 is operated in the rf-only mode at an elevated pressure to effect collision-induced dissociation for MS/MS experiments.

and operates with just rf drive voltages applied (Fig. 6.2), and thus, ions of all mass-to-charge ratios above a certain value are transmitted. There have been few changes to the triple quadrupole since they were first described in the 1970s and essentially all the changes have involved modifications of q2. The present triple quadrupole mass spectrometers often use a hexapole or octapole as the ion guide. Although these higher order fields are not suitable for mass analysis because of the coupling in the ion motion in the x - and y -dimensions, while each dimension is independent in a quadrupole field, they have a wider range of transmission in the rf-only mode [8,9]. The other change in q2 that has become common is a mechanically nonlinear rod set, so that there is not a line of sight from the ion source to the detector. Because the ions follow the centerline of the field, it is possible to do anything from having a small bend [10] in the ion guide to making a 180° curve.

6.3.2.1 MS/MS Efficiency. A key performance feature that made the triple quadrupole a success compared to the sector instruments used at that time was the increase in MS/MS efficiency. MS/MS efficiency (Eq. 6.6) is defined as the ratio of summed product ion abundance (ΣD) to the initial parent ion abundance before activation (P_0).

$$E_{\text{MS/MS}} = \frac{\Sigma D}{P_0} \quad (6.6)$$

The triple quadrupole has MS/MS efficiencies of 1–10%, which are typically 10–100 times greater than those of the sector instruments. There are several reasons for the increased MS/MS efficiency in triple quadrupoles compared to the sector instruments, which were the principal MS/MS instruments at the time of the development of the triple quadrupole. The major factor leading to improved MS/MS efficiency is the rf-only ion guide (q2) in which the CID reaction takes place providing strong focusing for ions after collision with a neutral gas. Thus, even if the ions are scattered substantially in the collision with the target gas (typically N₂ or Ar), product ions or undissociated parent ions are refocused back to the center axis and efficiently transmitted to Q3 for mass analysis. Because of the focusing characteristics of the rf-only ion guide, higher pressures of collision gas can be used than in older non-rf-confined collision cells, allowing a higher number of collisions between the parent ion and target gas, which further improves the MS/MS efficiency. Finally, an often overlooked effect is the time frame of the experiment. The transit time through q2 is on the order of hundreds of microseconds. This is in contrast to sector instruments where the CID process occurs in a time frame closer to 10 μs. Thus, kinetically slower reactions occur in the triple quadrupole that are not observed in sector instruments, which can further increase the MS/MS efficiency.

6.3.2.2 Modes of Operation. One of the key advantages of triple quadrupole mass spectrometers is the multiple types of MS/MS experiments that can be readily implemented. By far, the most common MS/MS experiment is the product ion scan. This scan is used to obtain structural information on ions in the mass spectrum with the goal of identifying the structure of the neutral compound from which the ion was formed. In a product ion scan, an ion formed in the ion source (parent ion) is selected in Q1

by fixing the values of the rf and dc voltages applied to the Q1 rods; the parent ion is reacted in q2, typically using CID; and then the product ions from the reaction are detected by scanning Q3 in the normal mode.

While any tandem mass spectrometer is capable of readily performing such product ion scans, triple quadrupole instruments are unique in their capability to perform other types of MS/MS experiments. In addition to product ion scans, triple quadrupoles can perform parent ion scans and neutral loss scans. The parent ion scan and neutral loss scans are used to screen for targeted compound types in a mass spectrum. For example, m/z 149 is a characteristic product ion of phthalates. By just reversing the modes of operation of Q1 and Q3, a parent ion scan is performed that will detect all the parent ions that dissociate to produce a product ion at m/z 149. This means that Q3 has fixed values of rf and dc voltages and Q1 is scanned in the normal manner.

The neutral loss scan, is useful when a compound type loses a common neutral fragment, such as phosphorylated peptides losing 98 Da (H_2PO_4). In a neutral loss scan, both Q1 and Q3 are scanned in the normal manner, but the scans are offset by the neutral mass of interest (e.g., 98 for singly charged and 49 for doubly charged phosphorylated peptides). This offset means that if the rf and dc voltages are at values to transmit m/z 656 through Q1, the Q3 rf and dc voltages would be set to transmit m/z 558 (singly charged ions) or m/z 607 (doubly charged ions). Thus, if m/z 656 dissociates by the loss of 98 Da, the product ion will be transmitted through Q3 and detected. If it loses any other mass (e.g., 120 to give an ion at m/z 536), that ion will not be transmitted and there will be no output signal from the detector. Because these scans are performed using identical hardware and need only specific software written to control the electronics via computer, all these scans can be implemented on any commercial triple quadrupole mass spectrometer.

In addition to the above scanning modes of operation, another very useful mode of operation is reaction monitoring. In reaction monitoring experiments, Q1 and Q3 are operated in a static mode to filter all ions but one parent ion and one product ion. This mode of operation is termed as *selected reaction monitoring (SRM)*. SRM scans maximize the sensitivity for the detection of known or targeted compounds in complex mixtures. Multiple SRM experiments can be performed where Q1 and/or Q3 vary, but do not scan. One form of MRM provides increased specificity. Q1 is fixed to transmit a given parent ion, while Q3 “hops” between selected mass-to-charge ratios of known product ions. The specificity is increased not only due to the detection of multiple product ions but also by the ratio of the intensity of the product ions. Another form of MRM involves both Q1 and Q3 hopping between predetermined parent ion and product ion mass-to-charge ratios. This approach can be implemented to screen for multiple targeted compounds in a single sample. This is often used for quantification where one parent ion is the target analyte (e.g., drug metabolite) and the other compound is an internal standard. Commonly, the internal standard will be an isotopically labeled version of the target analyte. In this case, if the isotope label is lost as a neutral, only Q1 will need to be changed, by the mass of the isotopic label, while Q3 will be held constant because the product ion will have the same mass-to-charge ratio for both parent ions. If the isotopic label or part of the label is retained in the product ion, both Q1 and Q3 will be hopped.

An important but subtle consideration in performing these various MS/MS experiments is the transit time of the ions through each quadrupole. As an example in the case of an MRM where Q1 is rapidly switched between the parent ions m_1 and m_2 ,

the rate at which Q1 can be switched is limited by the time it takes product ions to transit through q2 and Q3. In the event that Q1 is switched too rapidly from parent ion m1 to parent ion m2, product ions of m1 could be identified as having come from m2 if m1 and m2 share common product ions. In the case where m1 and m2 have different product ions, the scan speed will be limited by the time it takes for ions to be transmitted through to the detector, as any product ions present in Q3 when the mass is switched will be lost and sensitivity will be reduced.

6.4 QUADRUPOLE ION TRAP MASS SPECTROMETERS

6.4.1 Origin

Although the 3D quadrupole ion trap was first described at the same time as the quadrupole mass filter and used for trapping charged particles in physics experiments and to study ion–molecule reactions, it took several decades before it became a useful mass spectrometer. The transition from a quadrupole mass filter to a 3D quadrupole ion trap can be visualized as taking the quadrupole rod assembly and bending it into a vertical circle, joining the entrance and exit ends of the rods. The two rods in the vertical plane will form a donut-shaped ring, while the two rods in the horizontal plane will each form an “endcap” that is solid with a hyperbolic surface. Figure 6.6b shows the electrodes taken apart, and Fig. 6.6a is a cross-sectional drawing. It should be noted that to transfer ions into and out of the quadrupole ion trap, holes have to be drilled in the endcap electrodes. These holes, along with the fact that the electrodes do not extend to infinity, cause the electric field to deviate slightly from an ideal quadrupole field. These deviations can be expressed in terms of higher order fields, which can have positive and negative effects on the operation of the ion trap [11].

The key challenge to the development of the quadrupole ion trap as a mass spectrometer was an efficient way to detect mass-selected ions. Ions with stable trajectories in a quadrupole mass filter pass through the quadrupole to a typical mass spectrometry detector, an electron multiplier. Conversely, ions with stable trajectories in a quadrupole ion trap remain in the ion trap, and it is necessary to make them unstable to eject them to a detector. A simple but elegant solution to this problem was developed by Stafford and colleagues [12] in the early 1980s and led to the commercialization of the quadrupole ion trap by the Finnigan Corp. Operating the quadrupole ion trap with only an rf drive voltage means ions of increasing mass-to-charge ratio can be made sequentially unstable and ejected by increasing (ramping) the amplitude of the rf drive voltage. Because there is no dc voltage, the Mathieu a_u parameter is zero, and whether an ion has a stable trajectory or not is determined by the Mathieu q_z parameter. As noted in Fig. 6.4, ions with a $q_z < 0.908$ have stable trajectories. From Equation 6.3, q_z is proportional to the amplitude of the voltage (V) and inversely proportional to mass-to-charge ratio. For a given V, the mass-to-charge ratio that has a q_z of 0.908 is known as the *low mass cutoff*. As V is increased, the low mass cutoff increases and ions of increasing mass-to-charge value are ejected in the z -dimension. Placing an electron multiplier outside the electrode assembly on the z -axis allows the ions to be detected. This mode of operation is termed as *mass-selective instability*. While commercial quadrupole ion traps no longer use mass-selective instability, this invention catalyzed the development of the quadrupole ion trap mass spectrometer.

Figure 6.6 A cutaway schematic of a 3D quadrupole ion trap mass spectrometer. (a) Ions are injected into the ion trap through one of the endcaps and ejected through the other endcap to an electron multiplier for detection. (b) A three-dimensional model of the hyperbolic trapping electrodes commonly used in commercial 3D traps.

The original quadrupole ion traps were not even called mass spectrometers. They were marketed as Ion Trap Detectors™ and were used for gas chromatography/mass spectrometry. A rather unique operating feature of the quadrupole ion trap is the improvement of both resolution and sensitivity when operating with helium bath gas pressures in the millibar range [12]. The improvement in performance is a result of collisionally cooling the ions to the center of the electrodes that leads to more efficient ejection of the ions to the detector.

6.4.2 Ion Manipulation in Quadrupole Ion Traps

The power of the quadrupole ion trap lies in the ability to manipulate the trapped ions in time. The parameter that allows the ions to be controlled is what is termed the *secular frequency*. At a given set of operating parameters, V and U , ions of each mass-to-charge have a unique frequency at which they move in the z - and r -dimensions. For

a given drive frequency, Ω , the secular frequency is determined by Equation 6.7

$$\omega_u = \frac{\beta_u \Omega}{2} \quad (6.7)$$

where β_u is given in Equation 6.8:

$$\begin{aligned} \beta_u^2 = a_u + & \frac{q_u^2}{(\beta_u + 2)^2 - a_u - \frac{q_u^2}{(\beta_u + 4)^2 - a_u - \frac{q_u^2}{(\beta_u + 6)^2 - a_u - \dots}}} \\ & + \frac{q_u^2}{(\beta_u - 2)^2 - a_u - \frac{q_u^2}{(\beta_u - 4)^2 - a_u - \frac{q_u^2}{(\beta_u - 6)^2 - a_u - \dots}}} \end{aligned} \quad (6.8)$$

which for $q_z < 0.4$ and $q_r < 0.2$ can be approximated by Equation 6.9:

$$\beta_u = \sqrt{a_u + \frac{q_u^2}{2}} \quad (6.9)$$

The plot in Fig. 6.7 shows the iso- β lines, that is, sets of values of a and q that give a constant β and thus a constant secular frequency of ions of a given mass-to-charge ratio. The limits of the stable trajectories are actually bounded by $\beta_u = 0$ and $\beta_u = 1$ (as noted in Figs. 6.2 and 6.4), so ions will have a secular frequency up to one half the drive frequency, Ω . From a practical perspective, only the secular frequency in the z -dimension is useful. Because in the typical operating mode of quadrupole ion traps $U = 0$, Equation 6.9 reduces to Equation 6.10.

$$\beta_z = \frac{q_z}{\sqrt{2}} \quad (6.10)$$

Figure 6.7 Upper part of the Mathieu stability diagram for a quadrupole ion trap showing the iso- β lines. These lines are plots of a and q values that correspond to a given secular frequency. The secular frequency is the main parameter used to manipulate ions in a quadrupole ion trap.

The ions in a quadrupole ion trap are manipulated by applying a supplemental rf voltage at the secular frequency of the ions to the endcaps (z -dimension).

When the frequency of the supplemental rf voltage is the same as the secular frequency of a given mass-to-charge ratio, the ions that are in resonance will absorb power. This is termed as *resonant excitation* and increases the kinetic energy of the resonant ions. Resonance excitation is the key to almost every aspect of experiments performed in quadrupole ion traps. When resonance excitation is large enough, the ions will gain sufficient kinetic energy to be ejected from the trapping region; this process is often called *resonant ejection*.

Resonant ejection is how all commercial quadrupole ion trap systems obtain mass spectra, as it provides several advantages over mass-selective instability. First, it allows a larger range of mass analysis. With mass-selective instability, the ions have to reach a q_z value of 0.908 to be ejected and detected. With standard-sized electrodes (e.g., $r_0 = 1.0$ cm) this leads to a practical upper mass-to-charge ratio limit of around 1000. By performing resonant ejection at a lower q_z value, the mass range is extended proportionally. This allows the mass range to be extended to the 2000–4000 range, although much higher is possible [13]. The actual scan is analogous to the mass-selective instability scan, ramping up the rf drive amplitude so that the ions sequentially come into resonance and are mass-selectively ejected, from low to high mass-to-charge ratio, with the applied supplemental rf voltage. Another advantage of resonant ejection for mass analysis is increased resolution. A somewhat unique capability of the quadrupole ion trap is the ability to change resolution by changing the scan speed. By reducing the rate at which the rf drive voltage is ramped, the relative width of the peak is decreased, increasing the resolution [14]. For significant gains in resolution, the ramp rate must be drastically reduced, making impractical the simultaneous collection of a wide mass range and high resolution mass spectra. However, for narrow ranges, such as the isotopic distribution of a multiply charged ion, the slower scan is useful to obtain resolution allowing charge-state determination.

6.4.3 Linear Quadrupole Ion Traps

The linear ion trap, or 2D ion trap, is a quadrupole mass filter that traps the ions in two dimensions, x and y (or radial), using the rf drive voltage and traps ions in the axial dimension (z) with a dc voltage. The major advantage of the 2D ion trap versus the 3D ion trap (quadrupole ion trap) is the efficiency of ion injection. In the quadrupole ion trap, because there is an rf field in all three dimensions, the ions must be injected through an rf electric field. Only during a small phase angle of the rf cycle are the voltages compatible with efficient injection. Also, the injection is very sensitive to the amplitude of the rf potential. However, with the 2D ion trap, there is no rf electric field in the axial dimension, and as a result, ions can be injected over all 360° of the rf cycle. This leads to substantial reduction in the time required for ion injection.

Once in the trapping field, there is very little difference in the way ions are trapped in a 2D ion trap and a quadrupole ion trap. The Mathieu stability diagram also applies for 2D ion traps, and in the absence of dc potentials applied to the quadrupole rods, ions with a $q_z < 0.908$ are trapped radially. Ions will be prevented from exiting axially by applying to an electrode at the exit of the 2D trap a dc voltage slightly greater than the entering ions' kinetic energy. These blocked ions then turn around and travel back toward the lower dc potential applied at the entrance of the 2D trap. This dc potential

is lower than the ions' kinetic energy when they are entering the 2D trap. However, collisions with the bath gas will have reduced the ions' kinetic energy, so by the time ions return to the entrance, too little kinetic energy remains to overcome the entrance barrier and they will be trapped axially.

There are two means of implementing dc axial trapping. The most common method involves using plates/lenses with apertures at the front and back of the quadrupole rod assembly. This truncates the rf electric field, introducing higher order fields near the entrance and exit of the rods. Alternatively, short sets of quadrupole rods can be used in front of the entrance and at the exit of the main trapping rod assembly. The rf voltage can be capacitively coupled to the end segments, yielding minimum distortion of the rf electric field in the center segment, which is where the ions typically reside. Simulations of the electric fields obtained when applying a supplementary resonance excitation voltage to a pair of rods resulting from these two designs are presented in Fig. 6.8 [15]. Although the resulting electric fields generated by these two approaches result in only minor differences for trapping ions, they are significant for mass analysis.

One approach to mass analysis with the 2D ion trap is very similar to resonant ejection used in the quadrupole ion trap [15]. In this case, a supplementary rf voltage is applied to a pair of rods opposite to each other to resonantly eject the ions radially. Slots must be machined into the rods to allow the ions to exit to external electron multiplier(s). Homogeneity of the field is essential in this design, and thus, the use of end segments and precise alignment of the rods are critical. This design is the basis for the Thermo linear ion trap systems [15]. Although ions are ejected through both opposing rods to which the resonant frequency is applied, this is a highly efficient form of mass-selective ion ejection. In some cases, two electron multipliers are used to increase detection efficiency.

Figure 6.8 Simulation results showing the dipolar electric field in a single-segment 2D ion trap and in a three-segment 2D ion trap. The nonlinearity of the field where the end plate truncates the electric field can cause axial ejection. In a three-segment ion trap when the ions are trapped in the center segment, this is not a problem. In a single-segment ion trap, the axial ejection can be used to mass-selectively eject the ions axially.

An alternate mass analysis method takes advantage of the higher order fields that result from truncating the rf electric field with an aperture plate to perform axial ejection [16]. As noted earlier, ion motion in higher order fields is coupled; that is, when an ion is excited in one dimension, the initial kinetic energy gain is in that dimension, but it can then couple into other dimensions. This is in contrast to a pure quadrupole field where an ion increases its kinetic energy (and amplitude of motion) only in the dimension of the resonance excitation voltage. In the axial ejection 2D traps, ions are bunched toward the exit of the 2D ion trap and resonantly excited in the radial dimension. The increase in radial motion is coupled into axial motion, and the ions gain enough axial kinetic energy to overcome the dc potential at the trap end plate, resulting in ejection and detection by the electron multiplier. The coupling of radial excitation to axial ejection is not as efficient a process as radial excitation and ejection but more than 20% of the ions can be detected. This method of mass analysis is used in the AB Sciex Q-Trap[®] systems.

Another form of axial ejection has been introduced by researchers from Hitachi [17]. In this implementation, vanes are added between the quadrupole rods that produce a field that is approximately harmonic along the central axis. Ions can then be axially resonated and ejected. This is a more efficient ejection process than coupling between radial and axial motions but is still not as efficient as radial resonant ejection.

6.4.4 Tandem Mass Spectrometry

In the quadrupole ion trap, the different stages of the MS/MS experiment are performed in the same analyzer volume but at different points in time. Thus, MS/MS in trapping instruments is sometimes referred to as being *tandem-in-time*. A key feature of tandem-in-time experiments is that multiple stages of MS/MS (MS^n) can be performed. MS^n is not going to be specifically discussed here, but it can be a very powerful experiment to obtain ion structure/differentiation of isomers.

6.4.4.1 Ion Isolation. There are a number of approaches to isolating the parent ion in a quadrupole ion trap. To isolate parent ions of a given mass-to-charge ratio, ions of both lower and higher mass-to-charge ratios must be ejected. Lower mass-to-charge ions that have a $q_z < 0.908$ at the maximum amplitude of the rf drive voltage can be ejected by simply ramping the rf drive to a sufficient amplitude such that low mass-to-charge ions are ejected at $q_z = 0.908$. Higher mass ions can be simultaneously ejected during the ramp to ejection ions with mass-to-charge ratios less than that of the parent ion by applying a supplemental rf voltage at a frequency corresponding to a mass-to-charge ratio just higher than that of the parent ion at the start of the ramp. As the rf drive amplitude increases, sequentially higher mass-to-charge ions will be resonantly ejected, while those masses lower than the parent ion are ejected via mass-selective instability.

To this point, only single frequency resonance excitation waveforms have been considered. However, there is no reason that waveforms with multiple frequencies cannot be used. A standard means for manipulating ions with a waveform containing multiple frequencies is known as *SWIFT*, which is the acronym for Stored Waveform Inverse Fourier Transform [18]. In SWIFT, a frequency domain waveform is generated to achieve the desired purpose of the ion manipulation, for example, to eject all ions except parent ions for an MS/MS experiment. Such a waveform includes all secular

frequencies except those of the parent ion. Then, an inverse Fourier transform of the frequency domain spectrum is performed to obtain a time domain supplemental rf voltage signal that can be applied to the quadrupole ion trap. This time domain signal will cause all the unwanted ions in the quadrupole ion trap to be ejected. Very complex ion manipulation can readily be performed by this method, but one has to be careful in how the waveform is calculated, that is, the phases of the time domain signal must be such that a physically unattainable amplitude is not produced mathematically.

A simple way to approximate a SWIFT waveform is to add a series of sine waves separated by 500 Hz over the range of the resonant frequencies of ions (0 to one half the rf drive frequency). Then the frequencies of the parent ion can be “notched” out. Because the parent ion q_z value is controlled by the rf drive amplitude, a constant value of q_z for parent ion isolation can be used by changing the rf drive amplitude to set the parent ion at the desired q_z for isolation, and thus, the same waveform is applicable to all parent ions.

6.4.4.2 Ion Activation.

6.4.4.2.1 Collisional Activation. Several methods can be used for ion activation, each with different advantages and limitations. The most common form of activation is by collision with a neutral target gas as part of the overall process known as *CID*. There are several methods to induce energetic collisions between ions and neutral gas molecules where kinetic energy can be converted into internal energy. As mentioned earlier, the deposition of internal energy into parent ions leads to dissociation and formation of product ions, from which structural information can be deduced.

The type of dissociation products observed in collisional activation methods used in ion traps can be different from those observed in beam-type mass analyzers. It should be noted that the collision energy in a quadrupole ion trap is ill-defined. The ions' kinetic energy is constantly changing due to the dynamic nature of the electric trapping field, the acceleration of ions due to supplemental voltages, and the deceleration of ions due to collisions with the He bath gas. While the collision energies in triple quadrupole instruments can be similar in magnitude to those in the quadrupole ion trap, two fundamental differences often lead to different MS/MS spectra being observed. First, helium is typically the collision gas in the quadrupole ion trap, whereas nitrogen or argon is more commonly used in triple quadrupoles. With heavier gases as the collision gas, much more kinetic energy can be converted to internal energy per collision (Eq. 6.5), leading to a different internal energy distribution. The second difference between the quadrupole ion trap and triple quadrupole is the time frame for the reaction. Ions must dissociate (react) in 100 μ s or less in the triple quadrupole instrument to be observed in the next stage of analysis. However, in ion traps, the times are two or three orders of magnitude longer. This longer time frame allows low internal energy, but kinetically slow reactions to occur, and in fact can significantly favor such reactions.

6.4.4.2.2 Resonance Excitation. The first and by far the most common method for collisional activation is resonance excitation [19–22]. This method employs the same phenomenon of resonance as the resonance ejection method discussed previously. As noted above, when a supplemental rf voltage is applied to the endcap electrodes at an ion's secular frequency, that ion's kinetic energy increases. The difference between excitation and ejection is one of degree. By judiciously choosing the amplitude of the supplementary rf voltage and the time it is applied, the ion's kinetic energy can be

increased without supplying sufficient energy for ejection because kinetic energy is also lost from collisions with the He bath gas. A typical excitation voltage would be a few hundred millivolts (peak-to-peak) and 10–40 ms long.

Unfortunately, determining the frequency needed for resonance excitation is not always straightforward. The equation for determining the secular frequency of an ion (Eq. 6.8) is not exact. The resonant frequency is affected by higher order fields and can change as the ions gain kinetic energy [23]. The number of trapped ions also affects the secular frequencies of those ions [24]. The sum of the charge within the trapping volume or the “space charge” of the ions acts as a dc potential. The effective a_z value no longer equals zero, and the secular frequency shifts (Eq. 6.9). To address this problem, most commercial quadrupole ion traps are designed to control the number of ions trapped. Alternatively, the rf drive amplitude can be scanned over a narrow range.

Once the appropriate frequency is determined, the ion’s kinetic energy can be increased. However, one must be cautious of the competition between ejection and excitation [22]. If too much energy is supplied, a significant fraction of the parent ion population can be lost through ejection. The MS/MS efficiency is then decreased. This not only hampers the identification of the product ions but also limits subsequent stages of MS/MS due to an insufficient number of ions.

To favor excitation over ejection, the parent ion should be trapped as strongly as possible. The ions can be thought of as being held in an energy well, called the *pseudopotential well*. The “depth” of this well is the maximum kinetic energy the ion can have and still remain trapped. The deeper the well, the more kinetic energy the ion can gain before ejection. Ions in deeper wells can undergo more energetic collisions as well as a greater number of collisions. This allows the ion to gain enough internal energy to dissociate before it is ejected. The depth of the well, D , is related to the q_z parameter and can be approximated by the Dehmelt pseudopotential well model for q_z values less than 0.4 (Eq. 6.11).

$$D = \frac{q_z^2 m r_0^2 \Omega^2}{32e} \quad (6.11)$$

This equation shows that ions trapped with higher q_z values reside in a deeper well and can be excited to higher kinetic energies without being ejected. By increasing the rf drive amplitude, an ion’s q_z value can be increased (Eq. 6.3). However, at higher q_z values, the q_z values of lower mass-to-charge ions may exceed 0.908 becoming unstable, so the smaller mass-to-charge product ions are not trapped if they are formed. To balance between the well depth and trapping of the product ions, a q_z of 0.2–0.4 for the parent ion is generally chosen. As a result, product ions less than about one-third the mass-to-charge of the parent ion are generally not observed in CID experiments performed on trapping mass analyzers.

A variant of resonance excitation that allows lower mass product ions to be trapped is called *HASTE* (*high amplitude short time excitation*) [25] or *PQD* (*pulsed q dissociation*) [26]. The implementation of these techniques involves using a much larger amplitude resonant supplementary rf voltage (>1 V), but for a very short time (1–2 ms). The parent ion q_z value during the resonance excitation is similar or greater than that used in conventional resonance excitation, but as soon as the excitation step is complete, the rf drive amplitude is decreased to put the parent ion q_z at around 0.1, thus allowing the slow-forming low mass product ions to be trapped.

Another variation of typical resonance excitation CID involves the use of heavy gases (Ar, Xe, Kr) as the collision gas. Heavy gases offer the benefit of higher energy deposition per collision. As discussed earlier, the maximum amount of laboratory frame kinetic energy (E_{lab}) that can be converted to internal energy through a collision, E_{com} , is given by Equation 6.5. For a parent ion with a given E_{lab} , a heavy gas provides a higher m_t and a greater percentage of energy deposition than helium. The addition of heavy gas molecules to the quadrupole ion trap allows higher energy deposition and a greater degree of dissociation via CID. Also, the frequency range for efficient excitation is wider with heavy gases, reducing the required precision of the secular frequency [27]. With heavy collision gases, q_z values as low as 0.05 can be used, allowing low mass-to-charge products to be detected [28]. However, the heavy gas also deteriorates the mass spectral resolution and sensitivity of the quadrupole ion trap because of the greater scattering on collision during ejection. Pulsing in a heavy gas for CID and allowing it to pump away before detection can alleviate these problems at the cost of increased time per scan (reduced duty cycle).

6.4.4.2.3 Nonresonance Excitation. Frequency shifts due to the number of trapped ions are part of the motivation for finding other means of dissociation, although resonance excitation CID is still by far the most common method for ion dissociation. Controlling the number of trapped ions may be problematic if the ion source output fluctuates significantly, as can be the case with matrix-assisted laser desorption ionization (MALDI). This maybe one reason why no commercial quadrupole ion traps currently offer MALDI as an ionization option. One nonresonance technique less affected by the number of ions is boundary-activated dissociation (BAD) [29–31]. In this technique, a dc voltage pulse is applied to the endcaps instead of an ac voltage, causing a change in the ions' a_z values. As the a_z value become large enough, the ion's a and q points approach the boundary of the stability diagram. The a_z value is chosen so that the ion is not ejected, but because it is near the boundary, its trajectory increases in amplitude. As the ions' motions become larger in amplitude, there is greater force acting on the ions, causing their kinetic energy to increase. Collisions with the bath gas molecules can then lead to dissociation just as with resonance excitation. Only the magnitude of the dc must be adjusted to optimize the dissociation. As in resonance excitation, the ion must reside in a sufficiently deep well that the large-amplitude oscillations do not result in ejection. So, again, the q_z values used are typically between 0.2 and 0.4, and low *mass-to-charge* product ions are not observed. However, the secular frequency is irrelevant in BAD, so no tuning is required and any fluctuations in frequencies are inconsequential. Therefore, BAD is particularly useful for MS/MS when the ion intensity fluctuates significantly from scan to scan, as is common with MALDI.

Another activation technique using CID also involves a nonresonant approach [32]. Nonresonance excitation is capable of increasing an ion's kinetic energy to 40 eV and can do so in only a few microseconds. Like HASTE, the ions remain trapped with a higher kinetic energy than that that can be achieved via resonance excitation. Thus, the internal energy deposition can also be greater. This nonresonance excitation involves applying a low frequency square wave (50–500 Hz) to the endcaps. Because this frequency is so low in comparison to the secular frequencies of the ions ($\sim 100,000$ Hz), this square wave can be more reasonably thought of as a series of dc pulses. The square wave causes the trapping field to change instantaneously. The ions will accelerate quickly to compensate for this change. While doing so, collisions with the bath

gas convert the kinetic energy to internal energy. This process is repeated as the square wave cycles. Nonresonance excitation does not result in ejection because the kinetic energy added to the ions does not continuously increase the ions' periodic, stable motions as each of the previously discussed methods do. Instead, the ions change from one periodic motion to another very quickly. The kinetic energy is gained as the ions adjust from one motion to the other, not as a periodic motion is increased in amplitude.

Nonresonance excitation differs from resonance excitation in that it is not selective for any one species of ions. All trapped ions will be excited simultaneously. This can be desirable or not, depending on the application. Also, because more energy can be deposited quickly by nonresonance techniques, higher energy dissociation channels can be accessed. Thus, nonresonance excitation can form a different group of product ions from those seen with resonance excitation.

6.4.4.2.4 Infrared Multiphoton Dissociation (IRMPD). Another method for inducing dissociation differs from all the previously discussed techniques, in that it does not make use of collisions. Instead of increasing the kinetic energy of ions and then using collisions to convert that to internal energy, IRMPD uses photons to deposit energy into the ions [33–38]. IR-wavelength photons are sent into the trapping volume where they can be absorbed by the trapped ions. An IR-transparent window in the vacuum housing allows access to the trap. A laser beam can then be directed into a hole drilled through the ring electrode.

IRMPD offers several advantages over other dissociation techniques. First, it is not a resonance technique, and any ion in the path of the laser will be excited. This can be used, for example, to dissociate multiple analytes simultaneously. The laser beam will also excite product ions. These ions will subsequently dissociate and can provide a richer product ion spectrum. However, the spectrum can also be more complicated and hide the genealogy of the ions. The order in which product ions are formed in this type of MS/MS is not as clear as in stepwise MSⁿ.

One very important advantage of IRMPD is that low q_z values can be used. All other excitation methods described rely on increasing the kinetic energy to increase the internal energy of ions. Therefore, the ions must be able to absorb that kinetic energy without being ejected, which requires higher q_z values. IRMPD has no such restrictions, and low mass-to-charge product ions are easily trapped and observed. However, a complication with IRMPD in the quadrupole ion trap is that collisions with the bath gas molecules between absorption events can remove energy from the ions. If collisions occur quickly enough compared to the rate of photon absorption, the ions will not reach the critical energy for dissociation. All the early IRMPD experiments either reduced the bath gas pressure, which compromises sensitivity and resolution, or had a supplemental activation method concurrent with the IRMPD. However, recently, it has been demonstrated that appropriate focusing of the laser beam allows IRMPD to be performed at normal operating conditions without any supplemental ion activation [38].

6.4.4.3 Gas-Phase Reactions. Another type of MS/MS reaction for which trapping instruments are particularly useful involves gas-phase ion–molecule and ion–ion reactions. The quadrupole ion trap is particularly versatile for these types of analyses due to the combination of controlled timing of the reactions, mass-selecting capabilities for both reactants and products, and MSⁿ for both the formation of the reactants [39] and examination of the products [40]. Often, these reactions are between the trapped

ion and a volatile neutral introduced into the vacuum chamber. However, reactions between two ions have also been reported [41–45]. Ion traps allow the reaction to be controlled by holding the reactants together for a variable time before ejection and detection. Therefore, studying the kinetics is straightforward, and the extent of the reaction can be well controlled.

6.4.4.3.1 Ion–Molecule Reactions. Ion–molecule reactions in which a chemical reaction occurs rather than just the transfer of energy (CID) can be useful as a means of interrogating ions in a quadrupole ion trap. Reactions that are specific for a certain functional group or structure can be used to provide information about an analyte [46]. While ion–molecule reactions can be performed in a triple quadrupole instrument [47,48], the ability to easily control and vary the reaction time in a quadrupole ion trap allows additional information, such as reaction rate constants, to be determined.

Two simple ion–molecule reactions are hydrogen/deuterium (H/D) exchange and proton transfer. The gas-phase H/D exchange can be used to probe structures of ions, in particular, larger ions that may have multiple conformations [49]. H/D exchange is also useful in distinguishing functional groups [50]. While H/D exchange just comprises a change in mass of the analyte ion, proton transfer reactions involve transferring charge from the analyte ion to the neutral molecule. For singly charged ions, this is not a useful reaction, as a loss of charge results in the formation of a neutral that cannot be detected by the mass analyzer, but for multiply charged ions, deprotonation can be a very useful reaction [39]. [51]. There are thermodynamic limits to proton transfer ion–molecule reactions, which lead to the development of ion–ion reactions.

6.4.4.3.2 Ion–Ion Reactions. Reactions between two oppositely charged species can also be used. A quadrupole ion trap is particularly useful for these types of reactions, as both positively and negatively charged ions can be trapped simultaneously under normal operating conditions. Ion–ion reactions provide greater control in that ions are injected as needed, while neutral reactant molecules are usually present at a constant pressure. As with the ion–molecule reactions, deprotonation can also be achieved via ion–ion reactions. Ion–ion reactions have an advantage over deprotonating ion–molecule reactions, in that anions are much stronger bases than neutral compounds. Anions can completely deprotonate multiply charged proteins and peptides in ion–ion reactions, whereas neutral compounds used in ion–molecule reactions typically cannot. Ion–ion deprotonation reactions have been useful to determine charge states and to declutter charge-state convoluted spectra. By decreasing the charge on trapped ions, the mass-to-charge values shift. Where multiple charge states of proteins overlap, shifting to a lower charge state for each protein can separate the overlapping signals. Ion–ion deprotonation of multiply charged proteins can be done using fluorocarbon anions [43].

The ion–ion proton transfer reactions lead to the development of ion–ion electron transfer reaction [41,52,53]. Electron transfer dissociation (ETD) is becoming an increasingly popular method for the analysis of peptides and proteins. ETD is closely related to electron capture dissociation (ECD) [54] where a multiply protonated ion captures an electron to reduce the charge state by one. This reaction is exothermic and thus, after capture (or transfer) of the electron to the ion, dissociation can occur. When an electron is added to a multiply protonated ion, the resulting ion is a radical. The dissociation chemistry of radical ions is significantly different than that of even electron ions and thus ETD is often complementary to CID. A particular advantage

of ETD is that the dissociation chemistry has the ability to retain and identify sites of posttranslational modification [55–57]. In CID, functional groups added as posttranslational modifications to peptides and proteins are often facilely lost as neutral fragments and limited sequence information is obtained. With ETD, the radical dissociation chemistry is such that the posttranslational modification remains attached to the peptide/protein and typical sequence ions are produced. This allows identification of the site of posttranslational modification.

6.5 CONCLUDING REMARKS

The triple quadrupole mass spectrometer and the quadrupole ion trap mass spectrometer are probably the two most widely used instruments for MS/MS. Both are quite mature technologies, having been in existence for over 25 years. There are still improvements being made, but, in general, they are incremental and often more related to peripheral aspects of the mass spectrometry experiment rather than the actual mass analysis step.

The triple quadrupole instruments excel in the area of quantification and targeted compound analysis. The single reaction monitoring and MRM modes of operation of triple quadrupoles provide high duty cycles, maximizing sampling efficiency. Also, the quadrupole ion traps have some limitations in the area of quantification because of ion statistics. A limited number of ions can be trapped before space charge effects impact performance of ion traps. Development of 2D ion traps and newer 3D ion traps taking advantage of higher order fields have increased the ion capacity, but the triple quadrupole is still usually the instrument of choice for quantification.

The quadrupole ion traps excel in compound identification using MS/MS. The high sensitivity of ion traps combined with the fast scan rates and very high MS/MS efficiency make the ion trap uniquely compatible with chromatography/MS/MS experiments. quadrupole ion traps are also very powerful research instruments due to the variety and ease of implementation of ion activation methods.

Of course, triple quadrupoles and quadrupole ion traps do have limitations. In particular, neither the mass resolution nor mass accuracy is particularly high. While both these performance metrics have been improved over the years, in the near future, at least, quadrupole-based instruments will not compete in terms of resolution or mass accuracy with time-of-flight (TOF), ion cyclotron resonance (often referred to as *FTMS*), or orbitraps. However, one can get the best of all performance metrics by using hybrid instruments, that is, quadrupole-based analyzers combined with these other high performance analyzers. The hybrid QTOF instrument is similar in popularity to triple quadrupoles and quadrupole ion traps and the technology has been around about as long [58]. Quadrupoles interfaced with *FTMS* was also first reported over 25 years ago [59]. More recently, quadrupole ion traps combined with TOF [60,61], *FTMS* [62], and orbitraps [63] have become commercially available. Another hybrid instrument of importance is the hybrid triple quadrupole 2D ion trap. This is a multipurpose instrument that provides performance capabilities of a stand-alone triple quadrupole mass spectrometer along novel modes of operation that take advantage of a 2D ion trap [64]. As the instruments become more sophisticated and data systems more powerful, if cost is not a concern, only imagination will limit the possibilities. However, because of their MS/MS capabilities, it is likely that quadrupole-based analyzers will almost always have a role in mass spectrometry instrumentation.

7.1 SUMMARY

In the complex and expensive drug discovery and development process, characterizing metabolism and pharmacokinetic (PK) properties of new molecular entities (NMEs) is important to develop efficacious, safe, and rewarding drugs for patients. Among the analytical techniques used in the biopharmaceutical industry, assays based on liquid chromatography mass spectrometry (LC-MS) are highly sought out by the drug metabolism and pharmacokinetic (DMPK) scientists due to their sensitivity, selectivity, specificity, and speed. Several mass analyzer types have been used in DMPK studies, including quadrupole mass filters (QMFs), linear and three-dimensional ion traps (ITs), time-of-flights (TOFs), and Fourier transform mass spectrometers (FTMSs). Some of the desired qualities of the individual mass analyzer types and ion manipulation techniques are combined into one instrument to configure hybrid mass spectrometers. Such hybrid mass spectrometers become even more selective and specific when either a TOF- or a FTMS-based high resolution mass spectrometer (HRMS) is combined with either ITs or QMFs. HRMS-based hybrid mass analyzers, including Q-TOFs, linear ion trap-orbitrap (LIT-OT), and QMF-OT, have begun to become frontline mass spectrometers across the biopharmaceutical industry, especially in the DMPK laboratories. The focus of this chapter is on strategies based on hybrid mass spectrometers and procedures available for detection and characterization of xenobiotics at various stages of drug discovery and development.

7.2 INTRODUCTION

The study of metabolism is an integral part of drug discovery and development for understanding absorption, distribution, metabolism, excretion, and toxicological (ADMET) properties of an NME. Identification and characterization of structurally diverse metabolites or drug-derived materials can be challenging because they are usually present in low concentrations (nM to μ M) within complex *in vivo* or *in vitro* matrices that consist of lipids, proteins, or other endogenous materials. In recent years, liquid chromatography coupled with mass spectrometry (LC-MS) [1–4] has emerged as an important analytical tool for the separation, detection, characterization, and quantification of drug-derived materials from drug metabolism studies [5].

7.3 DRUG METABOLISM STUDIES IN SUPPORT OF DRUG DISCOVERY AND DEVELOPMENT

7.3.1 Discovery Stage Studies

The study of drug metabolism is a very important part of drug discovery, which helps in the optimization of metabolism properties of NMEs, in parallel with the optimization of their potency and efficacy. One of the earliest high throughput assays in the discovery stage determines the metabolic stability of NMEs, using human and/or animal liver microsomes or hepatocytes. Metabolic stability of an NME can be measured by means of quantitation assays that monitor the rate of disappearance of the NME (over a window of time at fixed time points) by utilizing a mass spectrometer [2,3,6]. These types of assays are often referred to as *high throughput-ADME (HT-ADME) screening assays* [7]. Higher throughput, robust, cost-effective screening assays have been developed in the recent years to cater to the increasing amount of NMEs in early discovery [6,8–13]. These assays use rapid, generic, fast gradient LC-MS/MS methods for the analysis of samples of CYP inhibition, Caco-2, permeability, efflux transport evaluation, protein binding, hepatocyte clearance, and isozyme profiling [14,15].

Although identification of metabolites may not be required for all compounds in early discovery, it may be useful to utilize highly sensitive mass spectrometers [LIT, QIT (quadrupole ion trap), TOF, Q-TOF, LTQ-Orbitrap (LTQ-OT)] that can be operated in full scan mode, data-dependent MS/MS mode, or targeted MS/MS mode with great selectivity and speed, which are very essential features to calculate the rate of disappearance of an NME and possibly metabolite formation. Since biotransformation of drugs usually leads to a change in molecular weight of the NME, metabolites formed can be determined by shifts in mass-to-charge (m/z) ratios as shown in Table 7.1.

Following HT-ADME screening assays, NMEs selected for further developments are filtered using *in vivo* PK screening assays. In order to accelerate the PK screening processes, automated sample preparation methods [solid phase extraction (SPE) and liquid–liquid extraction (LLE)], cassette dosing [16,17], cassette analysis [18–21], N-in-one dosing [22], and cassette-accelerated rapid rat screening (CARRS) [23] have been explored. Possibilities for obtaining metabolite data within PK screening assays have also been explored [19,20,24].

TABLE 7.1 Common Biotransformation Reactions and Associated Changes in Exact Mass and Elemental Composition

Biotransformation Reactions	Exact Mass Change (Da)	Elemental Composition Change
Hydroxylation/N-/S-oxidation/epoxidation	+15.9949	+O
Demethylation	−14.0157	−CH ₂
Deethylation	−28.0312	−C ₂ H ₄
Oxidative defluorination	−1.9957	−F + OH
Oxidative dechlorination	−17.9662	−Cl + OH
Dehydration	−18.0106	−H ₂ O
Dehydrogenation	−2.0157	−H ₂
Decarboxylation	−43.9898	−CO ₂
Ketone formation	+13.9792	−H ₂ + O
Methyl to carboxylic acid	+29.9741	−H ₂ + O ₂
Glucuronide conjugation	+176.0321	+C ₆ H ₈ O ₆
Sulfate conjugation	+79.9568	+SO ₃
Glycine conjugation	+57.0215	+C ₂ H ₃ NO
Cysteine conjugation	+119.0041	+C ₃ H ₅ NO ₂ S
N-Acetylcysteine conjugation	+161.0147	+C ₅ H ₇ NO ₃ S
Glutathione conjugation	+305.0682	+C ₁₀ H ₁₅ N ₃ O ₆ S

In late discovery, *in vitro* incubations in microsomes and hepatocytes are carried out for a cross-species comparison using both rodents and nonrodent species for full characterization of metabolites and determination of short- and long-term toxicological evaluation. It is advantageous to have HRMS-based instruments such as the LTQ-OT or Q-TOF or fast-scanning instruments such as the QTRAP to obtain both quantitative and qualitative data from metabolite profiling experiments [25–28]. An integrated streamlined process (METPRO) has been developed in our laboratories, which allows the identification of metabolites and the determination of kinetic parameters as well as profiles from a single analytical platform [29,30]. An alternative approach is to use the radiolabeled form of the NME (³H or ¹⁴C) [31,32] to conduct *in vitro* or *in vivo* experiments. Resulting samples are analyzed in parallel, using a split flow method, by a radioactivity detector (RAD) (online or off-line) and a mass spectrometer. This simultaneous detection of all drug-derived materials by an LC-MS and a RAD provides confirmation of the molecular weight and structural information of all radioactive peaks in a sample. Concurrently, the RAD provides quantitative estimates of all drug-derived materials in the absence of reference standards for quantitation using LC-MS.

Preclinical screening for reactive metabolites is an important tool to predict potential toxicological liability of an NME before progression into development. Characterization of glutathione conjugates and acyl glucuronides in discovery assists in early avoidance of structural liabilities that may lead to adverse effects. Experimental and mass spectrometric methods used in such reactive metabolite screen are the subject of recent publications [33–38] and are discussed in the chapter titled **Matrix-Assisted Laser Desorption/Ionization**. Another aspect of studying metabolites is to carry out reaction phenotyping studies [39] and to identify the enzymes responsible for the metabolism of an NME [40,41]. In later stages of discovery, the radiolabeled form of

the NME is used to carry out bile-duct-cannulated (BDC) studies in rodents or other toxicological species. These studies provide a semiquantitative estimation of the NME absorbed and metabolites formed under *in vivo* conditions, including information about conjugated and reactive metabolites [42].

In recent years, advances in *in silico* modeling have made it possible to screen compounds for undesirable ADMET properties, preferably before synthesis, which saves time and is also more economical for drug discovery. *In silico* methods such as Admet Predictor, Pre-ADME, ChemSilico, KnowItAll, and Pharma Algorithms help in predicting properties such as permeability, elimination, half-life, plasma protein binding, and oral bioavailability [43–46]. However, these techniques are fairly new and require extensive development and validation investments before they can be used as a predictive tool for optimization in drug discovery and drug design. The *in silico* models for metabolite predictions can be classified as being local or global. The global methods are empirically based expert systems that follow expert rules for predictions and include META, MetabolExpert, TIMES, MetaDrug, KnowItAll, and Meteor [47–49]. Local methods such as Compact and Camitro are based on the quantitative structure–metabolism relationships (QSMRs) and are derived from physiochemical, structural, or quantum mechanical properties [50,51].

7.3.2 Development-Stage Studies

In a developmental setting, drug metabolism studies are carried out with greater rigor, and cross-species comparison of *in vitro* (liver microsomes, S9 fraction, hepatocytes, and/or tissue slices) metabolites, nonclinical ADME studies, and human ADME studies are performed using the radiolabeled (^{14}C or ^3H) form of the NME [31]. Unlike the discovery stage studies, the *in vitro* and nonclinical ADME studies are carried out at more pharmacologically relevant doses. Among the nonclinical ADME studies, mass balance studies provide information about elimination routes, biotransformation pathways, and possibly gender-related differences in metabolism. Traditionally, mass balance studies are conducted around the same time as first-in-human (FIH) studies, but the timing of these studies can be delayed until after the proof-of-concept or clinical phase II studies.

In order to circumvent the late-stage attrition of NMEs, due to lack of efficacy or safety of the drug molecule, microdosing (1/100 of the pharmacologically effective dose) of radioactive drugs in clinical testing is supported by the US FDA or the EMEA to precede phase I studies and are called *phase 0* or *Exploratory IND* studies. Highly sensitive instruments such as accelerator mass spectrometry (AMS) and positron emission tomography (PET) are useful for the analysis of PK samples from microdosing studies. Even though the AMS technique can quantify ^{14}C -labeled compounds with attomole (10^{-18}M) sensitivity, additional chromatographic fractionation and separation needs to be carried out for the metabolites and NMEs before analysis is carried out by AMS. To overcome this limitation, the fast-scanning QTRAP 5500 hybrid mass spectrometer has been utilized to analyze samples from microdosing studies [52–54]. The combination of SRM-IDA (selected reaction monitoring–information-dependent acquisition) and list of possible metabolites were used to quantify the NME and to identify potential metabolites [55].

The efficacious human dose is predicted by scaling factors (e.g. allometric scaling) using PK and pharmacodynamic (PD) data derived from *in vitro* and *in vivo* studies

[56,57] for IND-enabling toxicological studies and FIH studies. Among the FIH studies single ascending dose (SAD) studies are carried out with small groups of patients to monitor for adverse side effects. Dose levels are escalated based on the early SAD studies to reach maximum tolerated dose (MTD) [58]. The next step is to carry out multiple ascending dose (MAD) studies to better understand the PK and PD of the NME. In addition to PK parameters and parent exposure, regulatory authorities (FDA/EMA) recommend determining circulating metabolites in humans and exposure to the same metabolites in preclinical species undergoing toxicological evaluations [59,60]. However, differences in LC-MS responses for a structurally related NME and its metabolites limit direct quantitation of metabolites during metabolite detection and characterization experiments. Ideally, the synthesis of an authentic standard is required for quantitative estimation of a metabolite by LC-MS. As cost- and resource-effective alternatives, several groups have evaluated techniques based on UV [61,62], collision-activated dissociation (CAD), LC-captive spray ionization (CSI) [60,63], NMR [64], radioactivity [65,66], and nano/micro-ESI [67–70] to analyze samples from SAD and MAD studies. These alternative techniques have been demonstrated to provide semiquantitative estimates of the metabolites in the absence of reference standards. A human ADME study is carried out before phase III to determine the total disposition of the NME [71,72], including mass balance, routes of metabolite/NME elimination, and biotransformation pathways. Metabolite identification and profiling from the ^{14}C -RAD profiles also help in correlating the results obtained from the SAD/MAD studies and nonclinical species undergoing toxicological studies [72].

7.4 MASS ANALYZERS IN SUPPORT OF DRUG METABOLISM STUDIES

Some of the common goals of drug discovery and development metabolism studies include detection, characterization, and quantitation of drug-derived materials in biological samples. The five commonly used mass analyzers at various stages of drug discovery and development can be classified into two categories: beam-type analyzers (TOF, magnetic sector, and QMF) and ion trapping analyzers (quadrupole and ion cyclotron resonance) [73]. Each of these analyzers has distinct capabilities of mass resolving power, mass accuracy, mass range, linear dynamic range, speed, and ionization compatibility [5]. The need to develop more efficient and high performance mass spectrometers has led to the advent of hybrid mass spectrometers, which coalesce the potential (or qualities) of multiple analyzers and ion manipulation devices into one instrument.

An important aspect of drug metabolism studies is the correct structural elucidation of metabolites, which can be achieved by utilizing tandem mass spectrometry (MS/MS). Hybrid instruments can also be classified as tandem-in-space instruments, in which both mass analyzers are physically separated, and tandem-in-time instruments, in which ion trapping, manipulations, and detection are achieved in sequentially timed events. Tandem-in-space instruments include sector instruments in forward or reverse geometry, Q-TOF, and Qq-LIT (QTRAP); tandem-in-time instruments include Fourier transform ion cyclotron resonance (FTICR) and ITs. The newest generation of hybrid mass spectrometers, for example, LIT-FTICR, LIT-OT, and QMF-OT combine aspects of tandem-in-space and tandem-in-time MS/MS experiments.

7.4.1 Nonhybrid Mass Analyzers

7.4.1.1 Quadrupole Mass Filter (QMF). The QMF or analyzer was developed in parallel with the QIT. A quadrupole mass analyzer consists of four parallel rods that have fixed DC and alternating RF potentials applied to them. Ions produced in the source of the instrument are then focused on and passed along the middle of the quadrupoles. Their motion will depend on the electric fields so that only ions of a particular m/z will have a stable trajectory and thus pass through to the detector. The RF and DC potentials are varied to allow ions of different m/z to pass through to the detector and thus build up a mass spectrum. Stand-alone single quadrupole mass spectrometers are often not used in drug metabolism studies because these types of mass analyzers lack the ability to perform MS/MS (MS^n) experiments to provide structural information about drug metabolites. On the other hand, a triple quadrupole mass analyzer, constructed using two QMFs and a multipole collision cell, can be utilized for acquiring full scan as well as MS/MS spectra. Because triple quadrupoles are tandem-in-space mass spectrometers, they are not ideally suited for performing sequential MS^n experiments. As shown in Table 7.2, SRM, product ion scans, constant neutral loss scans (CNLSs), and precursor ion scans (PISs) allow triple quadrupole mass spectrometers to be ideally suited for the quantification of parent NMEs (PK) as well as for identification of unknown metabolites.

Triple quadrupole mass spectrometers are the choice of instruments for majority of the preclinical and clinical PK studies, as well as metabolic stability studies, due to their high sensitivity and specificity for quantitation in the SRM mode. The mass range of the instrument is from 30 to 1800/2000 Da, and fragmentation patterns using collision-induced dissociation (CID) results in direct bond cleavage and formation of metastable ions, resulting in rich spectra. Triple quadrupole mass spectrometers are the choice of instruments for metabolic stability studies due to their high sensitivity and specificity for quantitation experiments using SRM mode [74–77]. Despite the high sensitivity in the SRM mode, triple quadrupoles are not ideally suited for detection and identification of metabolites due to low resolution, poor duty cycle, and low full scan sensitivity. If an NME series or an NME exhibits undesired PK properties in triple-quadrupole-based metabolic stability screening assays, metabolite profiling studies are initiated as a second-tier assay using samples obtained from higher drug concentrations. Incubations with higher NME concentrations are required to detect molecular ions of metabolites using low sensitivity Q1 or Q3 scan (full scan) of triple quadrupole mass spectrometers. During the early 2000, ThermoFisher redesigned the TSQ700 and TSQ7000 series triple quadrupole mass spectrometers to keep the RF as high as possible at the maximum RF voltage to achieve higher mass resolution. Although the new TSQ Quantum series triple quadrupole mass spectrometers provided a mass resolution >5000 , the higher resolution mode of operation still required slower scan speeds and scarification of sensitivity [78]. To improve sensitivity by transmitting higher number of ions from an ion source into the Q1 region and to provide some options to scan faster, the electrodynamic ion funnel technology, introduced by Smith and coworkers [79,80], has been incorporated with triple quadrupole mass spectrometers. However, the inability to perform MS^n experiments and to provide HRMS with liquid chromatographically suitable scan speeds limits the utility of triple quadrupole mass spectrometers in the mainstream metabolite identification laboratories.

TABLE 7.2 Summary of Triple Quadrupole MS/MS Scanning Modes for LOR (m/z 383.2) and its Major Fragment Ion of m/z 259.1

Scan Type	MS1 (Q1) Function	Collision Cell (Q2) Function	MS2 (Q3) Function	Purpose
Product ion	Parent or precursor isolation (e.g., for LOR, m/z 382.7–383.7) FIXED	Fragmentation of a narrow selected range of ions (e.g., for LOR, m/z 382.7–383.7)	Separation of fragments (e.g., for LOR, m/z 50–393) SCAN	Structural elucidation
Precursor ion	Passes a wide window of ions (e.g., 280–900 Da for LOR) SCAN	Fragments a wide window of ions (e.g., for LOR, 280–900 Da)	Set for a particular fragment (m/z 275 generated by oxidation of the m/z 259 fragment ion of LOR) FIXED	Structurally related unknowns/metabolites from complex biological matrix
Neutral loss	Passes a wide window of ions (e.g., 250–950 Da for LOR) SCAN	Fragments a wide window of ions (e.g., for LOR, 250–950 Da)	Separates a wide window of ions (Q1 and Q3 are offset by the neutral; 176 for all glucuronide metabolites of LOR or its metabolites) OFFSET SCAN	Structurally related unknowns/metabolites from complex biological matrix
SRM/MRM	Parent or precursor isolation (e.g., for DL, m/z 310.6–311.6) FIXED	Fragmentation of a narrow selected range of ions (e.g., for DL, m/z 310.6–311.6)	Set for a particular fragment (e.g., m/z 258.6–259.6 for DL) FIXED	Quantification

Abbreviations: LOR, loratadine; DL, desloratadine; MRM, multiple reaction monitoring.

7.4.1.2 QIT (3D Trap). The QIT analyzer utilizes a cylindrical ring and two endcap electrodes to make a 3D quadrupolar field capable of selectively trapping or ejecting ions. Although the fundamentals and concept of QIT were realized in the late 1950s by Wolfgang Paul and coworkers, difficulty in machining the hyperbolic electrodes and slower scanning mass-selective stability mode of operation limited the use of QIT to only physics research laboratories. In 1983, George Stafford and coworkers at the Finnigan Corp contributed to the advancement of QIT technology by incorporating (i) mass-selective instability mode of operation and (ii) bath or damping gas (i.e., helium) [81]. The new incorporations improved resolution, peak shape, trapping efficiency, and MS/MS time efficiency of QIT mass spectrometers. During the 1990s, because of the advances in machining technology combined with mass-selective instability mode of operation in the presence of damping gas and the ease of coupling to liquid chromatography, compatible ionization sources allowed QIT technology to develop into an analytical tool of choice for structural elucidation. A decade ago, drug discovery stage systematic approach to metabolite characterization and identification involved triple quadrupole and QIT mass spectrometers as frontline instruments [2]. Some of the advantages of using QIT for full scan MS and MS/MS experiments are listed in Table 7.3. A similar approach involving triple quadrupole and QIT mass spectrometers was also used in development-stage metabolite identification studies in support regulatory filings of several drugs, including desloratadine [82], lonafarnib [83],

TABLE 7.3 Comparison of Scan Modes and Associated Sensitivity When Using a Quadrupole Ion Trap and Quadrupole Mass Filter Mass Analyzers

Scan Type	QIT	QMF	QIT vs QMF
Full scan (Q1 or Q3, or 100–1100 Da) Total scan time = 1 s	A group of ions (m/z 100–1100) will be trapped for 750 ms and then emptied within next 250 ms. Trap will repeat the same process 20 times over a 20-s wide peak.	In any given time, ions of one m/z are present and allowed to pass through a QMF to the detector and all other ions are rejected. So, each m/z will be allowed to pass for 1 ms.	750 ms/1 ms = 750 QIT is 750 times more sensitive
Full scan product ion (MS/MS, 100–500) Total scan time = 1 s	Same as above, a group of ions are trapped for 750 ms; isolated, fragmented, and detected within a second. So, each m/z is collected for 750 ms.	Each m/z is sequentially scanned to the detector for 2.5 ms (1 s/400 Da = 2.5 ms/Da)	750 ms/2.5 ms = 300 QIT is 300 times more sensitive
SRM	Ions will be collected for 750 ms and then isolated and fragmented. Duty cycle is <75%.	Q1 and Q3 are set to pass a single m/z . Duty cycle is 100% because no scanning is required (10–250 ms per SRM).	A QMF provides an order of magnitude better LOQ for quantification experiments than a trap

Abbreviation: LOQ, limit of quantification.

saxagliptin [84,85], sitagliptin [86,87], prasugrel [88], clenbuterol [89], and dasatinib [90]. Although QITs are ideally suited for qualitative analysis, a number of groups have demonstrated the utility of QIT for simultaneous qualitative and quantitative analyses of metabolites and drug-related species [91]. To provide additional options for simultaneous qualitative and quantitative analyses, Bruker has introduced an ultrasensitive IT (amaZon™) with dual ion funnel technology, which has a scan speed of 52,000 Da/s at better than a unit resolution, for fast UPLC applications and maximum duty cycle in data-dependent MS/MS and MSⁿ. It can achieve mass resolving power up to 20,000 in full scan mode across the 50–3000 *m/z* range. Zero Delay Alternating™ acquisition allows high speed ion polarity switching without compromising sensitivity and speed. Up to 20 Hz MS data acquisition in both polarities is ideal in combination with fast ultrahigh pressure liquid chromatography (UHPLC) separations. It is also supported by spectral MSⁿ libraries for MS/MS-based multicomponent screening. Over the 10-year span from 1995 to 2005, QIT mass spectrometers were preferred for metabolite profiling workflow due to their excellent sensitivity, high speed (duty cycle), compact footprint, ease of use, ease of coupling to HPLC, reasonable cost, and ability to carry out MSⁿ experiments [2,92]. Poor trapping efficiencies, limited dynamic range, and space-charge effects resulting from small trap volume limited the sustainability of QIT as a frontline instrument for metabolite identification studies. Additionally, low mass cutoff or the 1/3 rule for MS/MS as compared to triple quadrupole often limits the utility of QIT for unknown structural elucidation. However, if sufficient ion signal from a sample is available, one has the option to circumvent the low mass cutoff by performing MS3 or MS4 experiments for gathering information about low mass fragment ions.

7.4.1.3 LIT (2D Trap). LIT, which is also referred to as *2D trap*, was introduced in 2002 [93] as a stand-alone mass spectrometer, known as *LTQ*, or as a part of triple quadrupole (QTRAP) [94] and in 2005 as a part LTQ-OT or LTQ-FTICR [95]. This section mainly focuses on the stand-alone LIT, and the hybrid analyzers are discussed in later sections. LIT is a variation on the transmission quadrupole mass analyzer and is constructed such that the ions can be either analyzed immediately in full scan mode or used for trapping to carry out MS/MS experiments. This instrument has significant improvements with respect to trapping efficiency, ion capacity, scan speed, and sensitivity for MS/MS compared to traditional 3D ITs. Table 7.4 compares some of the DMPK analytical performance characteristics of a QIT and LIT with those from a triple quadrupole mass spectrometer [96]. Since 2002, several LIT models,

TABLE 7.4 Comparison of Performance characteristics of QIT, LIT, and Triple Quadrupole Mass Spectrometers

Mass Spectrometer	Scan Time	Points/Peak	RSD (%)	LOD (pg/μL)	LOQ (pg/μL)
LCQ Deca XP Max (QIT)	MS: 575 ms MS ⁿ : 1000 ms	3–5	10	1.0	2.5
LTQ (LIT)	MS: 80 ms MS ⁿ : 150 ms	15–18	<2	<1.0	<1.0
TSQ Quantum Ultra (QMF)	SRM: 35 ms	>50	3	1.0	2.5

Abbreviations: LOD, limit of detection; RSD, relative standard deviation.

Figure 7.1 Schematic showing the ThermoFisher dual-cell linear ion trap (LTQ-Velos) mass spectrometer and the optics used for transferring ions from the ESI source to the mass analyzer.

each with improved performance characteristics, have been introduced including LTQ classic, LTQ-XL, and LTQ-Velos. Overall, separating the LTQ cell into high pressure and low pressure regions for ion accumulation/manipulation and detection, respectively, allows LTQ-Velos to gain 2–5X in sensitivity and scan speed over LTQ-XL (Fig. 7.1). Improved scan speed (10 Hz) allows the LTQ-Velos to accommodate analytes separated using UHPLC as well as on-the-fly positive/negative switching for detecting phase I and phase II metabolites by either polarity mode. One of the limitations of LIT for structural elucidation is MS/MS spectra with limited fragmentation information and low mass cutoff. Comparison of imatinib MS/MS spectra obtained using triple quadrupole and LIT mass spectrometers is shown in Fig. 7.2 [97]. While the MS/MS spectrum of imatinib (m/z 494) from a triple quadrupole is information rich, that from LIT provides only a single major fragment (m/z 394). Subsequent MS/MS of m/z 394 fragment provides additional fragmentation information. The fast-scanning capabilities of LIT allows to circumvent the low mass cutoff limitation by performing a modified form of CID involving pulsing of the q -values (PQD). Under PQD conditions, resonant activation of a precursor ion is achieved (100 μ s vs 1–2 ms) with high RF amplitude. This, in turn, allows the RF amplitude to be lowered very quickly to values which allow trapping of the low mass fragment ions [98]. Overall, PQD is not as sensitive as CID but provides the option to obtain low mass fragmentation information [99,100]. Another advantage of LIT stems from its fast-scanning capabilities, which is the ability to collect simultaneous qualitative and quantitative information of metabolites and drug-related species [96].

7.4.1.4 TOF. TOF mass analyzers have ions gated from the source region by an electrical pulse, which are accelerated down a TOF tube and have the same energy, where the low mass ions travel at a higher velocity, reaching the detector quicker than the high mass ions. Owing to their narrow dynamic range, TOF instruments have limited application in quantitation experiments. TOFs have an unlimited mass range as the ions are not trapped (similar to the quadrupole, IT, or FTICR) nor are their flight paths curved (magnetic sectors), and their detection efficiencies induce practical limits of a

Figure 7.2 Comparison of imatinib MS/MS and MS³ information obtained using (a) triple quadrupole and (b) linear ion trap mass spectrometers. *Source:* With permission from Ref. 97.

few hundred kilodaltons. Several groups have evaluated stand-alone TOF analyzers for performing integrated qualitative and quantitative bioanalyses. One of the earlier evaluations using a micromass liquid chromatography–TOF (LCT) mass analyzer involved simultaneous quantification of drugs in rat plasma and confirmation of their metabolites based on accurate mass and elemental compositions [101]. Most recently, Nagele and Fandino [102,103] used LC-ESI-TOF with multiple column and fast liquid chromatography to study the metabolic stability of drugs and identify their metabolites (Fig. 7.3). Overall, stand-alone TOFs are seldom used in the mainstream metabolite identification

Figure 7.3 (a) Determination of metabolic stability of buspirone and (b) identification of five monooxy metabolites of buspirone by fast LC-TOF using an integrated qualitative/quantitative bioanalytical approach. After 20 min of incubation, about 80% of the buspirone was metabolized. (a) The metabolic stability plot was generated by plotting incubation time with respect to extracted ion chromatogram peak area for buspirone $[M + H]^+$ ($C_{21}H_{32}N_5O_2$) = m/z 386.2556. (b) Monooxy metabolites of buspirone $[M + H]^+$ ($C_{21}H_{32}N_5O_3$) = m/z 402.2505 were extracted from the full scan TOF-MS spectrum. Five monooxy buspirone metabolites were identified by accurate mass measurement and elemental formulae confirmation. *Source*: With permission from Ref. 102.

studies due to their inability to perform MS/MS experiments. However, TOF couples extremely well with pulsed ion sources such as matrix-assisted laser desorption ionization (MALDI), and its excellent characteristics of high mass resolution and duty cycle allows it to be coupled to another TOF, QMF, or ITs to generate tandem instruments, such as TOF-TOF, Q-TOF, or IT-TOF, respectively. Among these tandem mass spectrometers, TOF-TOF is ideally suited for MALDI imaging experiments and to study metabolites distributed across various tissue compartments [104–107]. Q-TOF and IT-TOF (see earlier discussion) mass spectrometers are predominantly used for metabolite identification studies or integrated qualitative and quantitative bioanalyses.

7.4.1.5 FTICR. The FTICR mass analyzer is capable of providing the highest resolving power among all available mass analyzers. The technique of ICR-MS was first published in the mid-1950s when it was demonstrated as the instrument for measurement of very small mass differences at very high precision [108]. The technique remained largely an academic tool until the application of FT methods by Marshall and Comisarow in the early 1970s [109,110]. It is now one of the most sensitive methods with unlimited resolution. Since ions are measured using frequencies characteristic of the m/z value within the ICR trap using a combination of magnetic field

and voltages, ions are not destroyed by ejection for detection. Therefore, the same ions can be measured over and over or subjected to multiple experiments, ideally MS/MS or MS^n for structural elucidation, as well as other gas-phase ion–molecule reactions. Because frequencies can be measured most accurately than ion current or TOF, mass measurements with sub-ppm mass accuracies and $>100,000$ mass resolving power are routine with FTICR-MS. However, for routine metabolism studies, stand-alone FTICR mass spectrometers are not considered as a mainstream mass analyzer due to practical limitations resulting from operational pressure requirements in the range of 10^{-8} to 10^{-10} torr. Conversely, the operational pressure requirements for stand-alone LITs and QMFs are in the range of 10^{-5} to 10^{-7} torr and make these types of mass spectrometers readily amenable to coupling with HPLC- and/or UHPLC-based high throughput assays.

7.4.2 Hybrid Mass Analyzers

The need to develop more efficient and high performance mass spectrometers has led to the advent of hybrid mass spectrometers, which coalesces the potential (or qualities) of multiple analyzers and ion manipulation devices into one instrument. For example, the ability of LITs and QMFs to operate in the vacuum pressure range of 10^{-5} to 10^{-7} torr makes these types of mass spectrometers ideally suited for coupling with TOF- and FTMS-based mass analyzers for capitalizing on their high resolution capabilities. Among the various hybrid mass analyzers, QTRAP, Q-TOF, and LTQ-OT have evolved as frontline instruments for drug metabolism studies involving metabolite profiling.

7.4.2.1 QTRAP. QTRAP is a hybrid instrument that combines the attributes of ITs and triple quadrupoles into a single mass spectrometer. The salient features of the QTRAP include the selective scans (CNLS, PIS, SRM) [111] of a triple quadrupole with high sensitivity, high speed (duty cycle), and full scan features of the IT, allowing both qualitative and quantitative analyses of metabolites [112–115]. Similar to stand-alone LIT (2D IT) mass spectrometers, which were developed to improve detection limits over traditional QIT mass spectrometers, QTRAPs also have greater ion storage capabilities, and trapping and storage can be carried out without space-charge effects, which leads to increased sensitivity. A QTRAP's ion path consists of three quadrupoles, where Q3 can be operated in a standard mass-resolving triple quadrupole mode or used as an LIT (Figure 7.4). The novelty of a QTRAP instrument is that it has retained the mass filtering capability and provided the functionality of the LIT. When the instrument is operated in the LIT mode, an entrance potential barrier and exit potential barrier is created axially to contain the ions. In addition, a radial RF field is applied to contain the ions. Fundamental instrumentation details are described in a paper by Hager [113]. A QTRAP is capable of scanning at 250–4000 Da/s and its resolution is dependent on scan speed. In contrast to 3D ITs, helium is replaced by nitrogen to cool the ions and carry out CAD for ion trap fragmentation. The instrument can be switched rapidly (in about 5 ms) between triple quadrupole and LIT scans, which allows the acquisition of both LIT and quadrupole scans in the same cycle. MS/MS experiments are carried out by the selection of the precursor ion in Q1 using quadrupole DC isolation. Fragmentation is then carried out in Q2 (high pressure linear acceleration collision cell), and the resulting fragment ions are collected in Q3, which is operated

Figure 7.4 Schematic of AB Sciex QTRAP mass spectrometer. IQ, interquadrupole lens; LINAC, linear acceleration high pressure collision cell. (See color insert.)

in the LIT mode. Since ion selection is carried out in Q1, the trapping efficiency is greatly increased for the analyte because Q2 is filled with the ions of interest only. The increased trap capacity of the LIT (nearly 70 $\times$) as compared to the QIT plays an important role in the increased sensitivity of the LIT. In addition, the collision cell in the LITs allows higher energy fragmentation compared to traditional traps, leading to a rich fragmentation spectra containing primary and secondary fragmentation pathways. Owing to the absence of the low mass cutoff, more fragments at lower mass range can be observed.

The LIT has a variety of scan functions, which are described in the following.

1. *MS*. Enhanced MS is carried out to obtain a full scan MS spectra or survey scan in a defined scan range. During the EMS scan function, Q1 and Q2 are operated in RF-only mode with no collision energy and ions are trapped in Q3 (LIT), which are then detected. EMS provides the most sensitive survey scan for subsequent MS/MS scans.
2. *EPI*. During an enhanced product ion, the precursor ion is selected in Q1, fragmentation is carried out in Q2, and ions are trapped in Q3 and then scanned out for generating product ion spectra. What makes the EPI scan one of the most sensitive MS/MS scan function is the concurrent trapping of ions in the Q0 region while the isolation, fragmentation, and detection events are occurring.
3. *ER*. Enhanced-resolution scan is used to obtain mass spectra at higher resolution, especially on the order of <0.25 Da. Mass resolving power in the range of 5000–6000 at m/z 700 is achievable with scan speeds of 250 Da/s.
4. *MS³*. This type of scan function involves precursor ion selection in Q1, fragmentation in Q2, and trapping precursor/product ions in Q3 before switching to the LIT mode of operation for RF/DC isolation of a product ion followed by single frequency excitation in Q3 (LIT mode) before generation of product ion spectra. The MS³ mode spectra exhibit low mass cutoff.
5. *EMC*. The enhanced multiply charged scan removes singly charged ions and enriches multiply charged ions. This function helps in removing signals due to background/matrix and improves S/N ratio.

6. *TDF*. Time-delayed fragmentation helps to diminish the amount of secondary fragment ions, which simplifies complex MS/MS spectra. Under TDF conditions, ions are activated en route from Q2 to Q3. In Q3, activated ions are allowed to thermally cool before fragment ions are collected. Early fragments are rejected using the LIT mode stability parameters, and the fragments are collected after a delay time. The user has time-delayed control over the mass range.

It is also important to note that QTRAPs provide the option to utilize a collision energy spread (CES) function that changes the collision energy during a trap fill and EPI scan. For example, if CE is set at 30 with a CES of 15, the MS/MS spectra will show all the ions from the fragmentation at 15, 30, and 45. This feature is useful while acquiring qualitative data to identify metabolites, where it can be difficult to predetermine the optimum collision energy to be used for acquiring the data.

The various scan modes available in the QTRAPs have made it possible for the identification and characterization of metabolites. The triple quadrupole and LIT scan modes can be utilized for a variety of experiments: EMS (LIT single MS mode), PIS based on parent fragmentation pattern or phase II conjugate loss (phosphate, sulfate charged loss), CNLS based on phase II neutral conjugate loss (glucuronide, glutathione), and theoretical SRM based on biotransformation of parent molecule [116]. These modes can be coupled with automatic product ion experiments (IDA) in the QTRAP, where acquisition of both triple quadrupole survey scans is followed by MS/MS spectra being acquired in the IT in an IDA manner.

Qualitative metabolite identification was first reported for gemfibrozil with an API 2000 QTRAP, and quantification was reported for propranolol in plasma samples [116]. Hager and Le Blanc [115] demonstrated that metabolite identification could be improved using selective triple quadrupole MS survey scans to trigger the product ion spectra using automated IDA. Triple quadrupole and LIT scan modes can be used in several ways: LIT single MS mode, PIS based on parent compound fragmentation or for phase II conjugates (glucuronide or glutathione), and theoretical SRM to monitor biotransformation reactions of the parent compound. Very detailed work on metabolite identification and quantitation has been presented by Hopfgartner *et al.* [117] for several compounds including trocade, tolcapone, and remikiren. The ability to utilize selective MS/MS scans helped identify metabolites in picogram levels in very complex matrices [117,118].

In more recent years, quantitative and qualitative profiling of endocannabinoids (ECs) in human plasma was performed by an IDA experiment with SRM as the survey scan and EPI as the dependent scan. This method was rapid, highly sensitive, and selective to assess quantitation and identify ECs [119]. Quantitative and qualitative workflows using QTRAP technology have been extended by Qiao *et al.*, [120], King *et al.*, [121], and Li *et al.*, [122]. The essence of these experiments is based on the selective triple quadrupole scans, sensitive product ion scans, and the ability to perform SRM for targeted and untargeted metabolites. Good agreement was observed between SRM only and combined full scan and SRM data. In summary, QTRAP is suitable for laboratories where quantitative PK/TK (toxicokinetic) bioanalysis is the main focus and occasionally selected samples or studies involving qualitative bioanalysis need to be handled. Overall, QTRAP QQQ mode of operation allows one to use the triple quadrupole mode SRM methods for targeted quantification while the scan

speeds achievable with the LIT mode of operation provide options for collection of nontargeted information about metabolites, degradants, impurities, and biomarkers.

7.4.2.2 Q-TOF. A schematic of a Q-TOF mass spectrometer is shown in Fig. 7.5. Q-TOF is a hybrid mass spectrometer where a quadrupole mass analyzer (excellent sensitivity for SRM experiments) is coupled with a TOF mass analyzer (high resolution and efficient duty cycle) and involves replacement of the Q3 of the triple quadrupole mass spectrometer with the TOF. In the recent years, there has been much improvement in scan speeds, dynamic range, signal-to-noise (S/N) ratio, resolution, and the coupling with UHPLC, making the Q-TOF an instrument where integrated qualitative and quantitative bioanalytical studies can be carried out with ease [123–127].

Ions generated from atmospheric pressure ionization (API) or MALDI are “gated” from the source region by an electrical field pulse and accelerated down the TOF tube. The ions with lower m/z values travel with a higher velocity than those with higher m/z values. The calibration of accelerating fields and resulting flight times provides mass analysis. Similar to any analytical instrument, the analyte’s mass accuracy is dependent on the mass axis calibration. This can be performed by external or internal calibration procedures. External calibration can be easily performed with all mass analyzers and is the most preferred option. Frequent calibrations are not required with nominal mass or low resolution mass spectrometers (triple quadrupoles and ITs) because the degree of mass accuracy is limited to >500 ppm. Similarly, mass measurements with <5 ppm mass accuracies are routine with most FTMS with periodic (monthly or semiannually) external calibration [128]. However, with TOF-based mass analyzers, mass measurements are impacted by temperature changes and related changes in the ions’ TOF within the field-free region. Therefore, frequent mass calibration is a critical component for achieving <5 ppm mass accuracy and is an essential daily routine to be performed before running batches of samples. Most modern Q-TOF systems can

Figure 7.5 Ion path for AB Sciex TripleTOF 5600 Q-TOF mass spectrometer.

be automatically calibrated using reference compounds that are stored in vials with software-controlled automated valves [129–131]. In the Waters Synapt Q-TOF, mass accuracy can further be improved by a reference mass (known as a *lock mass*) that is introduced via a second ESI probe to the ion source for analysis within each run [36,128]. Whenever resolution and mass range settings are changed, the mass calibration procedure should be repeated. Similarly, the TripleTOF 5600 (AB Sciex) has a unique calibrant delivery system that is programmed to automatically inject a calibration mixture, via an atmospheric pressure chemical ionization (APCI) probe, at regular intervals during the analysis of sample batches. This process is completely under software control, provided the user configures the instrument before the submission of sample batches. The instrument software automatically checks the resolution setting and instrumental parameters (MS and MS/MS) for the analytical run and calibrates the system if needed. This eliminates the need for user intervention when the instrument parameters and experiments are changed for multiple batch submissions especially during unattended overnight analysis.

As shown in Figs. 7.6–7.8, a collision cell is located between the quadrupole and the TOF analyzer to induce fragmentation in MS/MS experiments. The quadrupole can be used either in narrow-band pass mode for acquisition of MS/MS data on selected ions or in wide-band pass mode for all ions to enter the collision cell. When the ions are not selected, and only RF voltage is applied to the quadrupole, the ions will pass the collision cell without undergoing any fragmentation and will be analyzed by the TOF in full scan MS mode. Subsequent analysis of ions and fragments is carried out in the TOF analyzer, which uses either an analog-to-digital converter (ADC) or a time-to-digital converter (TDC) [132,133]. The Q-TOF systems from Agilent Technologies, Bruker Daltonics, and Waters are equipped with ADC-based detection techniques, whereas the TripleTOF 5600 (AB Sciex) is equipped with a TDC detector [126]. The linearity and mass accuracy of highly abundant ion signals are impacted when using TDC detectors because of the signal saturation and inherent dead time [129]. However, in newer TOF instruments, detector saturation is minimized by incorporation of dynamic ion transmission controls with unique gating technologies to modulate the flux of the ions entering the flight tube. An added advantage of the TDC detection system is a lower background noise compared to the ADC, which in turn provides better sensitivity and/or S/N ratio particularly for lower mass ions. The TripleTOF 5600 resolved most of the dynamic range limitations of TDC by incorporating a four-channel 40 GHz TDC detector and a 25 keV accelerating voltage combined with unique gating controls and fast electronics to produce 25-ps time resolution and mass accuracy across the full mass range [134].

Until the introduction of time-lag focusing in the mid-1980s and the reflectron in the mid-1970s, TOFs were considered a low resolution mass analyzer with a very limited dynamic range. Time-lag focusing improved mass resolution by simultaneously correcting for the initial spatial and kinetic energy distributions of the ions. The reflectron design, a common feature in today's TOF-based mass analyzers, corrects for the kinetic energy distribution of the ions. Collectively, implementation of time-lag focusing and the reflectron improved the resolution of TOFs from several hundreds to thousands [136,137]. Furthermore, improvements in mass resolving power and mass accuracy resulted from flight tube temperature stabilization, novel detectors, and fast

electronics [36,138]. Overall, the current Q-TOF mass spectrometer is an inherently fast technique and provides the user the option to collect full scan data as well as targeted MS/MS or information-dependent MS/MS data (Section 7.4.2.4). Availability of the full scan MS or survey scan data provides the flexibility to examine the data set using a wide array of postacquisition software for probing unexpected metabolites as well as biomarkers or degradants [139–142].

7.4.2.3 Orbitrap (OT). Various OT-based hybrid mass analyzers were introduced over the years, starting in 2005. OT utilizes electrical fields between sections of a roughly egg-shaped outer electrode and an inner electrode or a spindle, where the ions' orbit and their oscillation are recorded as image current on the spindle. Similar to FTICR, in OT, ions are measured using frequencies characteristic of the m/z values.

In contrast to FTICR, where a combination of magnetic field and electrostatic potentials is used to trap and manipulate the ions within an ICR cell, ions in OT are manipulated using a combination of electrostatic potentials. Since OTs measure motions of ions, similar to FTICR, it is important to maintain ultrahigh vacuum in the range of 10^{-7} to 10^{-8} torr. Ultrahigh vacuum requirements prevent OT from functioning as a stand-alone mass analyzer. However, ions from an API source can be first introduced into either an LIT or a QMF, which are capable of functioning at 10^{-5} to 10^{-7} torr before transferring into OT for analysis. Similar to any trap-based mass analyzers, the performance of an OT mass analyzer is also affected by space-charge effects, which occurs when too many ions reside in the IT, leading to a distortion of the electric field. This in turn can impact mass resolution, detection, and mass accuracy. The automatic gain control (AGC) procedure, implemented for minimizing space-charge effects, uses a short prescan to determine the ion current within the mass range of interest and enables the storage of a fixed number of ions ("AGC target value") in the following analytical scan [143,144]. This function is carried out by alternate prescan and analytical scans. If the prescan identifies an excessively high total ion current (TIC), the injection time for the consecutive analytical scan will be subsequently reduced. Typically, a user can select among three AGC target values: (i) 3×10^6 for a high dynamic range or to maximize quantitative performance, (ii) 1×10^6 for a balanced scan, and (iii) 5×10^5 for best mass accuracy in untargeted analysis.

Metabolic profiling of pharmaceutical entities requires comprehensive structure elucidation of the parent compound and its metabolites. The fragmentation of the parent drug is used as a reference, and the site of biotransformation or the "soft spot" can be determined after comparing the product ion spectra of the parent and the metabolite. Often, multiple MS/MS experiments such as MS^3 or MS^n experiments are useful in determining the metabolite structure. The availability of accurate, fast, and sensitive mass measurement and several CID fragmentation options allowed Lim *et al.* [135] to study the metabolism of carvedilol. In the workflow followed by Lim *et al.* [135], an LTQ-OT classic mass spectrometer operated at a resolving power of 60,000 was used to perform parent mass list triggered data-dependent MS^n accurate mass analysis. As shown in Fig. 7.6, the initial step to understand the fragmentation pathway of carvedilol and lineage of its product ions involved MS, MS/MS, and MS^3 experiments. Fragment ion structures proposed by Mass Frontier (fragmentation prediction software) were identified and confirmed using elemental compositions proposed by HRMS. At present, OT-based mass analyzers are standard platforms for detection, characterization, and identification of metabolites from *in vitro* and *in vivo* samples. Steady improvements have been made to OT platforms in two fronts: (i) increase scan speeds to accommodate separations based on UHPLC and (ii) provide richer fragmentation information for structural elucidation using alternate fragmentation techniques such as higher energy collision dissociation (HCD) and pulsed Q collision-induced dissociation (PQD). Improvements in scan speed and fragmentation techniques were achieved in the LTQ-OT VelosTM mass spectrometer (Figure 7.7) [145–147] and are discussed in Section 7.2.6.2.

As shown in Fig. 7.8, in the newly released hybrid OT mass spectrometer, Q-Exactive, the LTQ component of an LTQ-OT is replaced with a QMF [148]. Another way of looking at the new line of hybrid OT instruments is the mass selection capability provided in a stand-alone benchtop OT mass spectrometer "Exactive." The Exactive mass spectrometer has been explored for small-molecule quantitation [149]

and integrated qualitative and quantitative [141] workflows, but the lack of mass selection for fragmentation has thus far limited its application to selected areas in the DMPK arena. Unlike the LTQ-OT series of mass spectrometers, where switching between positive and negative HRMS modes of data collection can take hours, the Q-Exactive is capable of switching between positive and negative modes within minutes. Recent evaluations clearly show that Q-Exactive is ideally suited for high throughput screening with integrated qualitative and quantitative analyses. The Q-Exactive is capable of providing a resolution of 100,000 and 140,000 at m/z 400 and 200, respectively, and is equipped with an HCD cell for performing mass-selective CID experiments. Ions generated in the API source are transmitted using a QMF into a curved linear trap (c-Trap) or HCD cell before being transmitted into the OT for FT mass analysis. MS/MS data are collected using the QMF to select precursor ion of interest and HCD cell to perform CID experiments. Similar to any FT-based mass analyzers, mass resolution is dependent on scan speeds and for an ion at m/z 200, the resolution could vary between 10,000 and 100,000 with scan speeds between 10 and 1 Hz, respectively.

7.4.2.4 Metabolite Fragmentation Information. To eliminate the need to perform multiple injections of the same sample and utilize an array of mass spectrometric and chromatographic methods to decipher metabolism information and arrive at structural information about metabolites, Wrona *et al.* [150] and Bateman *et al.* [151] introduced the “All-in-One” or MS^E (where E represents the collision energy) experimental approach. In the MS^E approach, data is collected using two scan functions as shown in Figure 7.9. In the first function, Q1 is set to pass a mass range, for example, m/z 100–800, and Q2 is then set at a “low” collision energy (5 eV) that provides

Figure 7.9 All-in-One or MS^E (where E represents the collision energy) experimental approach. CNL, constant neutral loss; XIC, extracted ion chromatogram. Source: With permission from Ref. 150.

transmission of intact ions through the collision cell. These ions are pushed into the TOF analyzer and detected with high resolution [8000 full-width-at-half-maximum (FWHM)] and mass accuracy (<10 ppm). The second scan function also scans in the same mass range, but Q2 is set at a “high” (15–35 eV) collision energy that fragments all ions that are transmitted through Q1. Again, the product ions are detected by the TOF analyzer. Hence, two mass spectra, one with intact molecular ion information (“low energy” function) and other with fragment ion information (“high energy” function) are generated alternating low/high energy data acquisition (MS^E) in the wide-band mode. The advantage of obtaining full scan spectra is that comprehensive data for all metabolites and adducts can be generated, including doubly and singly charged adducts. Key diagnostic ions for accurate neutral losses and precursor ions can be selected by comparing the low energy and high energy fragmentation traces, especially for the detection of GSH adducts [152]. The mass window is set for ± 10 mDa. This narrow range allows high selectivity and excludes false positives from the matrix. Since all data is collected in one run, postacquisition processing of fragment ions is possible by a variety of data processing algorithms [153,154]. Other workflows with a similar theme to MS^E [150,151,155] include the recently demonstrated FragAll or MS^{ALL} [156] or SWATH [157,158]. Even though MS^E experiments can provide detailed information of the product ion spectra, it is sometimes difficult to determine the exact soft spot of a metabolite and it may be necessary to resort to a combination of MS-based techniques such as stable isotope labeling [5], H/D exchange [159], or even LC-NMR [26].

Several Q-TOF-based options are also available to acquire a combination of full scan and MS/MS data under UHPLC timescale (analyte peak widths 3–7 s) for adapting the combined qualitative and quantitative (qual/quant) workflow in the DMPK arena. The combined Q-TOF-based qual/quant workflow for DMPK applications was recently described by Ramanathan *et al.* [160], Ranasinghe *et al.* [134], Campbell and Le Blanc [161], and Fung *et al.* [162]. The qual/quant workflow can be implemented as shown in Figure 7.10. In the approaches shown in Figure 7.10, once a full scan HRMS spectrum is acquired, an MS/MS experiment can be triggered based on the criteria provided by the operator. The threshold-based MS/MS data collection method is referred to as *IDA* or *data-dependent acquisition*.

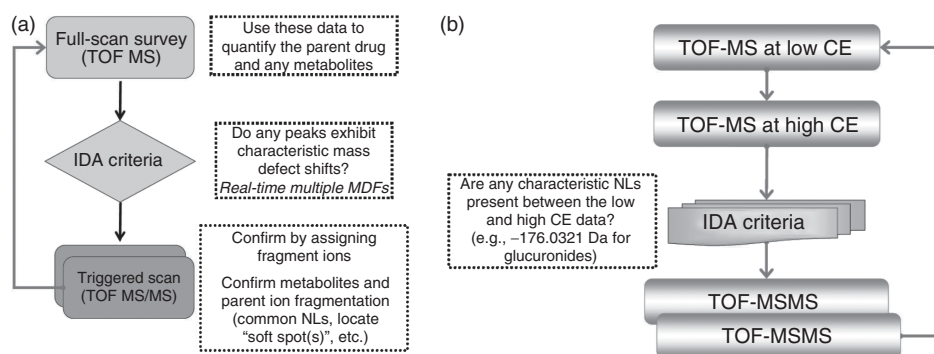

Figure 7.10 Two Q-TOF MS-based methods applicable for integrated qualitative/quantitative workflows. (A) Combination of TOF-MS survey scan and the on-the-fly mass defect filter (MDF)-triggered MS/MS or other information-dependent triggered MS/MS. (B) Coupled low- and high-collision energy (CE) experiments that can trigger a confirmatory MS/MS scan based on on-the-fly constant neutral loss (NL) detection. *Source:* With permission from Ref. 161.

Figure 7.11 Fragmentation options available in orbitrap (OT)-based mass spectrometers. (a) Exactive: no mass selection is available for CID experiments but non-mass-selective all-ion fragmentation is possible. (b) LTQ-OT Velos (CID): selection in time (trap-trap); mass selection and CID are possible in the LTQ (ion-trap-like fragmentation). (c) LTQ-OT Velos (HCD: selection in time (trap-trap); mass selection in the LTQ and CID in the HCD cell (triple-quadrupole-like fragmentation). (d) Q-Exactive: selection in space (filter-trap); mass selection using QMF and CID in the HCD cell. *Source:* With permission from Ref. 148.

Fragmentation options available in OT-based mass spectrometers are summarized in Figure 7.11. No precursor ion selection is available for CID experiments in a stand-alone OT or the Exactive but non-mass-selective all-ion fragmentation (AIF) is an option [163]. When AIF is used, the mass spectrometer collects alternating full scan MS and MS/MS scan spectra. Although the AIF feature is similar to the MS^E available on the Q-TOF mass spectrometers, deciphering the fragmentation pathways and linking the origin of each fragment is difficult without sufficient liquid chromatographic separation or precursor ion selected fragmentation [163]. As shown in Figure 7.12 and Table 7.5, three precursor ion selectable MS/MS options are available in the LTQ-OT Velos mass spectrometer: (i) CID, precursor ion selection and fragmentation in the LTQ and detection using either the LTQ (low resolution) or the OT (high resolution); (ii) PQD, time events are identical to CID but the Q-value is pulsed to enhance trapping of the low mass fragment ions; and (iii) HCD, precursor ion selection in the LTQ, fragmentation in the HCD cell, and detection using the OT. Recently, work from our laboratory demonstrated that small molecules (MW <600 Da) and their metabolites can be efficiently fragmented with high accuracy using both HCD and PQD [99]. In the example shown in Figure 7.12, the CID, HCD, and PQD spectra of hydroxywarfarin obtained using a LTQ-OT Velos mass spectrometer are compared. While some of the low mass fragment ions were absent in the CID spectrum, the fragmentation process under the CID conditions was efficient and most sensitive. The PQD spectrum showed a unique fragment ion at m/z 189.0181 that helped to narrow the site of hydroxylation, but one of the major fragment ions at m/z 179.0339 was absent. The MS/MS techniques available on the LTQ-OT Velos mass spectrometer can be rank-ordered based on the sensitivity results as CID > HCD > PQD. Overall, the HCD and PQD spectra were rich in fragmentation information and helped to narrow the site of hydroxylation.

Figure 7.12 Comparison of (a) CID, (b) HCD, and (c) PQD spectra for hydroxywarfarin obtained using an LTQ-OT Velos mass spectrometer.

TABLE 7.5 Fragmentation Modes in LTQ-OT Velos Mass Spectrometer

Activation Type	CID	HCD	PQD
Precursor selection	LIT	LIT	LIT
Collision cell	LIT	HCD	LIT
Collision gas	Helium	Nitrogen	Helium
Collision energy ^a	~35	40–75	35–60
Detection of ions	IT/Orbitrap	Orbitrap	IT/Orbitrap
Activation, Q-value	0.25(constant)	N/A	>0.6
Dissociation	single	single	3-step
Mass range	Low mass cutoff (“1/3 rule”)	No low mass cutoff	No low mass cutoff
Fragmentation	MS ⁿ	MS ²	MS ⁿ

^aNormalized collision energy.

7.4.2.5 Mass Defect Filtering. According to currently accepted mass measurement convention, the mass of carbon $^{12}\text{C} = 12.000000$ Da and the exact masses of all the other elements are either slightly higher or lower than their integral value. For example, the exact mass of $^1\text{H} = 1.007825$ Da and $^{16}\text{O} = 15.994910$ Da. The ^1H is therefore $+0.007825$ Da and ^{16}O is -0.00509 Da. Therefore, the term *mass defect* refers to the difference between the exact mass of an element or compound and its closest integer value [164]. Although the utility of mass defect for identifying isotopes

of elements was realized during the 1920s [165], the application of mass defect to filter drugs and their metabolites present in biological samples was only demonstrated very recently [35,151,166,167]. At present, mass defect filter (MDF) can be applied post acquisition on every HRMS platform and during real-time acquisition on selected platforms [161]. One of the prerequisites to use MDF is that data must be collected using high mass accuracy, high mass resolution, and full scan MS mode. A combination of high resolution measurement and the mass defect of the parent drug can be used to readily discern drug-derived ions from the background ions. Postacquisition application of MDF is demonstrated in Fig. 7.13. Comparison of unfiltered data (a) with those obtained using extraction window of m/z 400–600 (b) and MDF with a filter of 10 mDa above and 30 mDa below the fractional exact mass of the parent drug (c) shows that MDF clearly filters out all the background signal and sheds light on the drug-related components.

Another option is to apply MDF during real-time acquisition or “on-the-fly.” In the example shown in Figure 7.14, buspirone product ion at m/z 122.0713 was used to screen for metabolites or drug-derived components (precursors) forming a product ion with the exact mass of 122.0713 [134]. Detection of the product ion at m/z 122.0713 suggests that the pyrimidine moiety of buspirone is not modified. One of the advantages of this approach is the fact that the number of product ion spectra or the number of hits was low, and primarily related to the metabolites, due to the high specificity of the on-the-fly MDF [166]. On-the-fly MDF-triggered MS/MS is a bonus to postacquisition probing of the full scan data where MS/MS of the *in vivo* metabolites are not available unless the samples are reinjected and analyzed by targeted MS/MS experiments [134]. The mass defects and accurate masses of both product ions and the precursor ions confirm the site of oxidation, and the tentative structures of the *in vivo* metabolites are assigned. Although multiple MDF templates can be used to ensure metabolites outside the 100 mDa MDF window are not missed, in the approach shown in Fig. 7.14, single MDF/analyte was used for on-the-fly MDF experiments [168]. As a fail-safe approach, all full scan survey raw data files can be subjected to postacquisition multiple MDF.

7.4.2.6 Isotope Pattern Filtering. In addition to the option to apply MDF post acquisition, other advantages of acquiring full scan HRMS data include preservation of information about additional analytes from an analysis and preservation of isotopic patterns of analytes of interest and background ions. Pharmaceutical drugs that contain chlorine (Cl) or bromine (Br) or strategically introduced stable-labeled isotopes such as ^{13}C or ^{15}N at a known percentage generate a unique MS isotope patterns. Frequently, metabolites or degradants maintain a similar isotope pattern. Therefore, the isotope pattern can be used as a filter to discern drug-related components in complex biological matrices. In an IPF workflow, if an analyte contains chlorine (Cl), the relative abundances of the peak [A] or $[\text{M} + \text{H}]^+$ generated by the monoisotopic ions including the ^{35}Cl and isotopic peaks $[\text{A} + 1]$ and $[\text{A} + 2]$ generated mainly due to ^{13}C and ^{37}Cl isotopic contributions are examined, if the $[\text{A}]/[\text{A} + 1]$ and $[\text{A}]/[\text{A} + 2]$ peak ratios. If the isotopic pair ratios match the user-defined ratio then the components will be considered as drug-derived materials and extracted into the ion chromatograms or additional MS/MS experiments can be triggered for structural elucidation. Today, almost all HRMS platforms offer some form of postacquisition isotope pattern filtering (IPF) algorithm and selected vendors even offer on-the-fly IPF-triggered MS/MS options.

Figure 7.13 Application of “postacquisition” MDF as part of metabolite detection, characterization, and identification strategy for an extract of rat plasma following administration of a proprietary drug (L-006235): (a) unfiltered data, (b) extracted ion chromatogram (m/z 400–600), and (c) MDF using the fractional mass of the proprietary drug (L-006235) (XIC window $+10/-30$ mDa). *Source:* With permission from Ref. 151.

The IPF option has been explored to screen for reactive metabolites as well as to scout for drug-derived components. Ma *et al.* [169] evaluated the reliability and effectiveness of the IPF technique using an LTQ mass spectrometer. In this evaluation, human liver microsome incubations enriched with a 1:0.8 mixture of nonlabeled GSH/stable-isotope-labeled GSH were used to study GSH adducts of carbamazepine, diclofenac, 4-ethylphenol, acetaminophen, *p*-cresol, and omeprazole. Without utilizing HRMS techniques, Ma *et al.* [169] demonstrated that when employed as

Figure 7.14 Application of “on-the-fly” MDF as part of the integrated qualitative/quantitative bioanalysis to scout for metabolites in *in vivo* samples.
Source: With permission from Ref. 134.

a postacquisition data mining tool, the IPF technique was very powerful and effective in detecting low levels of GSH adducts. A similar workflow using a TOF-based mass spectrometer and brominated analog of glutathione, *N*-(2-bromocarbobenzyloxy)-GSH (GSH-Br), was evaluated by Le Blanc *et al.* [170]. In this study, GSH-Br was used to trap reactive metabolites formed following the incubation of acetaminophen, fipexide, trimethoprim, and clozapine in rat liver microsomes.

Lim *et al.* [171] used a LTQ-OT mass spectrometer and exploited HRMS in combination with ISP-triggered data-dependent product ion scan to successfully detect and characterize GSH conjugates of acetaminophen, tienilic acid, clozapine, ticlopidine, and mifepristone. To take advantage of the IPF workflow, human liver microsome incubations were carried out using a 2:1 mixture of nonlabeled GSH/ $^{13}\text{C}_2^{15}\text{N}$ -GSH. The IPF workflow used by Lim *et al.* [171] allowed not only the detection of GSH adducts but also the detection and characterization of cyano-*N*-methylene iminium ion conjugates of verapamil and its O-desmethyl metabolites. Recently, a similar accurate mass-based IPF method was demonstrated by MsMetrix [172], a company engaged in developing software tools for metabolite identification. In this approach, a 1:1 mixture of nonlabeled GSH/ $^{13}\text{C}_2^{15}\text{N}$ -GSH was used as a trapping agent to generate GSH conjugates with a unique (*A*) and (*A* + 2) doublet with an exact mass difference of 3.0037 Da. The MsMetrix approach was successfully used to detect GSH conjugates of clozapine, diclofenac, imipramine, and ticlopidine following incubation with human live microsomes. Most recently, Zhang *et al.* [173] evaluated the MsXelerator software, a software approach developed by the MsMetrix group, to detect and quantify GSH adducts. In this evaluation, various nonlabeled GSH/labeled GSH ratios were evaluated using LTQ-OT Velos and TripleTOF 5600 mass spectrometers. A ratio of 3:1 of nonlabeled GSH/labeled GSH was found to be sufficient to detect most GSH adducts. An attractive outcome of this study was that MsXelerator software was found to be capable of processing raw data files from multiple vendors and detecting GSH adducts without difficulty.

7.4.2.7 Software Tools for Metabolite Detection. The availability of various HRMS technologies discussed previously clearly shows that the acquisition of analytical data is no longer the bottleneck of metabolite detection, identification, and characterization. This limitation now falls in processing and interpretation of data sets to make meaningful conclusions, independent of instrument model, and beyond just the hybrid mass analyzers. The Waters MetaboLynx application manager runs the samples scheduled for analysis by LC-MS, detects expected/unexpected metabolites, and reports within a data browser mass spectrometric and chromatographic evidence for the automated metabolite assignment [125]. Software packages with similar capabilities include MetWorks (ThermoFisher) and MetabolitePilot (AB Sciex). These software packages provide opportunities for most scientists to decipher metabolism information from a sample rather than limiting the task to mass spectrometry or metabolism specialists. Most of these programs work by comparing two LC-HRMS raw data files, one is from the sample of interest (dosed or +NADPH) and another from a control (predose or placebo-dosed or -NADPH) sample. Drug-derived components are detected using user-defined MDF, IPF, or MS/MS criteria. Despite the limitations of the software packages, including the inability to produce a comprehensive list of all theoretically possible biotransformation processes of a drug and the inability to detect metabolites present at low levels, many software tools are being adopted widely and

consequently as their benefits are being realized. The current limitation of these software tools is the inability to process raw data files, both qualitative and quantitative, from multiple platforms or vendors. However, several software vendors including the MsMetrix and Mass-MetaSite groups are actively engaged with pharmaceutical scientists to develop instrument vendor neutral software tools [172–174]. Such software tools would be paramount for seamless functioning of a globalized scientific community involving multiple scientists from multiple functional areas accessing the same data file.

8.1 INTRODUCTION

Molecular imaging is one of the cornerstones of the experimental methods available for understanding the spatial complexity of biological tissues and cells. Ideally, imaging methods should provide detailed information of a number of tissue components and provide a resolution that surpasses that of individual cells. Most current methodologies often require *a priori* knowledge of the molecules of interest. Microscopy has long been one of the most powerful techniques to study the distribution of biologically relevant compounds in tissues. Immunohistochemical methods were first studied in 1942 in the work of Coons *et al.* [1]. They presented a method employing the specificity of an antibody labeled with fluorescein for the localization of antigens under a fluorescence microscope. It was a generic method for the histological localization of any antigen of interest. The antibody could be conjugated with simple chemical compounds without destroying its capacity to react with the antigen. One of the limitations of immunohistochemistry is that simultaneous visualization of different antigens can be very challenging and posttranslational modifications of proteins can be difficult to detect because of the lack of an available antibody specific for these modifications.

The ability of modern proteomic techniques to identify and quantify the levels of up to thousands of proteins from a tissue or biofluid sample has transformed medical and biological research. In addition to global protein profiling [2], methods have been developed that target protein isoforms [3,4] or their interactions [5], specific pathological entities [6], or subcellular components [7]. It has been increasingly recognized how the rich molecular information provided by this array of approaches offers new possibilities in the clinical field. This ranges from new insights into the molecular changes associated with pathogenesis, the identification of new therapeutic targets, to improved diagnosis

and prognosis through the determination of biomarker proteins and protein profiles associated with a disease and its progression [8]. Many clinical institutions have initiated research programs for the identification of disease biomarker proteins and protein profiles, mostly in easily accessible body fluids such as plasma, serum, and urine.

Difficulties associated with sample volume and complexity, dilution of the biomarkers, and the intrinsic variability of the protein content of body fluids have led to the alternative strategy of searching for biomarkers in the affected tissue. Recent notable examples include a combination of tissue microdissection, protein extraction, and extensive peptide/protein separation to quantitatively investigate the changes in protein content associated with the different stages of diseases [6,8].

Several groups have demonstrated how mass spectrometry (MS)-based methods can be directly applied to tissue. Rapid progress in the field now allows the parallel analysis of 100–200 proteins, high sensitivity and selectivity, and the ability to distinguish between close variants [9–11]. Histology-directed tissue profiling, in which localized MS is used to generate peptide and protein signatures of specific regions of a tissue previously annotated by a pathologist, has demonstrated how the signatures of the different regions can be used to classify the tissue [12,13]. These classifications, based on the nontargeted analysis of the peptides and proteins present in specific regions of the tissue, demonstrate the ability of this technique to acquire clinically relevant data. The candidate markers determined by these classifications are based on the levels of many peptides and proteins and provide an example of a general observation in biomarker research, namely, that a single protein biomarker may not be sufficient to annotate the complexity of real biological systems [14,15]. Protein profiling by imaging MS has been performed on human brain tumors [11,16,17], rat pituitary [18], mouse brain [19], mouse prostate [10], mouse epididymis [9], and in animal models for neurological disorders including Parkinson's disease [20] and Alzheimer's disease (AD) [21].

Imaging MS can be considered a spatially resolved direct tissue analysis and uses the same tools to simultaneously analyze the distribution of 100–200 proteins in tissue and to associate the differential protein images with histopathological analysis. Several studies have already shown how imaging MS can be used to chart the variation in protein content in pathological tissues and revealed that changes in distribution and biochemical content are widespread [22]. The spatiochemical information obtained directly from the tissue (thus not diluted by body fluids) and without prior knowledge of the sample's biomolecular content has great potential as a discovery tool to identify those changes associated with a specific diagnosis/prognosis. In many regards, it is the aim of imaging MS to become a peptide/protein screening that complements histopathological analysis.

Imaging MS comprises the collection of a mass spectrum at each of a regular series of points across the tissue section. Using these spectra, it is possible to plot the relative intensity of the individual m/z peaks in the mass spectrum across the tissue section, visualizing the distribution of the individual molecular ions. A two-dimensional map can be generated for each mass peak of interest in the mass spectrum and depicted as an intensity or pseudocolor heat map. Reproducible sample preparation, mass spectral acquisition, and data processing allow these maps to be compared between related samples to assess which biomolecular changes are associated with disease (and its progression). In current experimental workflows, the imaging MS analysis is aligned with an optical image of the tissue section (H&E stained after the imaging MS experiment) [23,24]. This allows the direct comparison of the specific biomolecules with the tissue's

morphology or the determination of the molecular content of histological regions of interest. Advanced data-analysis tools enable the data sets to be interrogated to reveal which peptides and proteins have similar profiles [25–27], which are correlated with specific histological features [27] and can be used to classify the tumor type of the tissue [27,28].

One main advantage is its lack of *a priori* knowledge since any compound of interest at the surface of the sample can potentially be detected. Imaging MS is very useful as a discovery tool where a tissue section can be investigated without knowing in advance what specific proteins have changed in a comparative study. Furthermore, imaging MS also allows the detection of posttranslational modifications, given that these generally involve mass changes. Unfortunately, many of the fixation approaches developed for optical and electron microscopy are not suitable for imaging MS, and so new MS-specific protocols have been designed, this is described in the following sections. Imaging MS has a significant potential to be used in a targeted approach as well, such as for monitoring drug delivery and metabolism. Imaging MS can visualize and distinguish the parent drug and its metabolites in contrast to autoradiography as no labeling is required.

While profiling MS of a tissue section can be of interest to analyze discrete regions of a tissue, imaging MS becomes necessary when the focus is the protein distribution information. The analysis of various cell types can be correlated to the tissue architecture, thereby enabling peptides and proteins specific to the tumor and/or adjacent stroma to be identified. High resolution images are desirable when a defined substructure is present; however, they may also be utilized as a discovery tool for a suspected yet otherwise not morphologically detectable transformation such as has been observed for tumor margins [29].

Immunohistochemical methods allow localization of antigens, antibodies, and numerous other cell and tissue components and have facilitated the development of specific diagnostic tests. Imaging MS offers the potential for the simultaneous analysis of many molecular species present in a single biopsy regardless of the availability of specific antibodies. Furthermore molecules spanning multiple molecular classes, which may be involved in a disease state, can be investigated. For clinicians, this will permit molecular assessment of tumor biopsies with the potential to identify subpopulations that are not evident based on the cellular phenotype determined microscopically [30]. In addition, this technology also permits imaging the distribution of low molecular weight compounds such as lipids, drugs, and metabolites, opening new possibilities for the measurement of concomitant protein changes in specific tissues after systemic drug administration.

Imaging MS has been used in a wide variety of applications since its development by Caprioli *et al.* in 1997 [18]. Improvements have been made in sample handling, spatial resolution, sensitivity, robustness, speed, and instrumentation, and molecular images up to a resolution of 5 μm can now be acquired. Today, imaging MS is applied in different research fields, from fundamental research to clinical applications (cancer research, neuroscience, and pharmaceutical research).

Imaging MS is increasingly used in clinical proteomics as a tool for candidate biomarker discovery. A large range of biomolecules, spanning multiple molecular classes, can be simultaneously analyzed without predefining the molecules of interest (e.g., labeling). This multiplex, nontargeted analysis enables a comparative analysis of the biomolecular content of diseased samples and, as such, may be used to complement

established histopathological practice. However, before imaging MS can be routinely used in a clinical setting, a large number of patient samples need to be compared to provide statistical foundation necessary for a new diagnostic tool. Good collaborations with pathologists and surgeons are crucial for ensuring the quality of the samples and the interpretation of the subsequent experimental results.

Designing an imaging MS experiment includes several important aspects that will optimize signal quality. Sample preparation for imaging MS plays a crucial role in generating reproducible quality data, and this is described below.

8.2 METHOD OVERVIEW

The workflow of a typical MALDI (matrix-assisted laser desorption/ionization) imaging MS experiment is given in Fig. 8.1, and all different steps are described in detail in this section. Sample handling, from the point of collection and isolation to the final data acquisition, is one among the most crucial steps in imaging MS for achieving qualitative and reproducible results. Goodwin *et al.* [31] have given a schematic representation of the MALDI imaging MS workflow, with an overview of which factors need to be considered to minimize variation and which factors can be used to optimize performance based on four different key stages (tissue collection, tissue cutting, tissue pretreatment, and matrix application), which we have discussed in the following paragraphs (Fig. 8.2). It is essential to maintain the integrity and spatial localization of the molecules in the original tissue. Since the introduction of imaging MS, many reviews have been published that address sample handling and sample preparation [30,32–37].

Figure 8.1 Schematic of the MALDI imaging MS workflow.

Figure 8.2 MALDI imaging MS workflow and the experimental factors that must be considered to minimize variation and optimize performance. The manual nature of these steps can make them highly prone to user artifacts unless stringent protocols are followed [38].

8.2.1 The Tissue Sample

The integrity of a tissue sample is key to any analysis of its biomolecular content. An imaging MS procedure starts with tissue collection, and this is the first important step toward high quality and reproducible results. Tissue collection must be performed in accordance with the appropriate ethical guidelines. It has been shown that postmortem changes can occur within minutes [31]. Techniques to limit the impact of postmortem degradation suppress enzymatic activity by denaturation of proteins, chemical fixation, or cryofixation. In animal studies, a common condition to preserve tissue morphology as well as the native distribution of biomolecules is that tissues must be rapidly dissected following animal sacrifice and flash-frozen in liquid isopentane or nitrogen. For the collection of tissue specimens derived from humans, standardized protocols and well-documented procedures should be agreed on/consulted with the surgeons and the pathologists. After freezing, tissues should be stored at -80°C .

The majority of the imaging MS studies have been performed on flash-frozen tissue sections, although recent developments have enabled imaging of formalin-fixed paraffin-embedded (FFPE) tissues [39,40]. Formalin fixation stabilizes proteins by

chemical cross-linking, thus preventing postmortem enzymatic proteolysis while maintaining the cellular histology [41]. FFPE tissue blocks are stored at room temperature. The cross-linked proteins are difficult to extract from the tissue with standard matrix application procedures. To circumvent the cross-linking induced by formalin fixation, a protocol based on ethanol fixation [42] or on RCL2/CS100 fixation (a non-cross-linking organic fixative [43]) in combination with paraffin embedding has been developed and proved to be suitable for proteomic analysis and tissue imaging. The advantage of using FFPE tissues for imaging MS is the large existing collections of FFPE tissues in hospital tissue banks: The ability to search for biomolecular signatures associated with specific pathological features and known clinical outcomes would represent a powerful tool for clinical biomarker research. However, in order to achieve this goal, it will be necessary to identify which tissues are still suitable for analysis, as the retrospective nature of the tissue banks means that many of the tissues may have been collected and processed using methods less suited to modern bioanalytical techniques.

After freezing, the tissue can be fixed to the cryostat stage using a droplet of water or 10% gelatin. The use of optimal cutting temperature (OCT) embedding media should be avoided as much as possible because this compound includes many water-soluble polyethylene glycol compounds that significantly interfere with the imaging MS experiment [32]. The potential interference from these compounds is such that if one is using a shared cryostat, the cryostat should be comprehensively cleaned before use. When an embedding medium is required for sectioning, 10% gelatin or agarose can be used [44]. The frozen tissues are then sectioned and transferred onto cold indium-tin oxide (ITO)-coated glass slides [45] or other holders suitable for imaging MS experiments. It is important to deposit the section uniformly without scratches [46]. The tissues are normally mounted onto the target plate or glass slide by gently heating the underside of the slide with a finger. Immediately after sectioning, the tissue section should be dried for at least 10 min in a vacuum desiccator to remove residual water from the tissue.

To date, the majority of imaging experiments has been focused on the analysis of thin frozen tissue sections. The sections, 5–50 μm thick, are collected at -5 to -25°C using a cryomicrotome. For each tissue, the cutting temperature may need to be optimized. Thicker sections are easier to collect; however, thinner sections have been shown to provide higher quality mass spectra [47]. When a study is set up, wherein multiple sections are required, it is recommended to collect these sections at the same time to prevent repeated handling of the tissue, although side effects such as oxidation may increase [38].

Goodwin *et al.* [31] showed postmortem degradation in brain tissue section. The intensity of a range of markers was seen to vary when tissue sections were kept on room temperature and on timescales of 30 s to 3 h; while some peptides/proteins were stable, the intensities of several peptides were found either to decrease (degradation) or increase (degradation product) (Fig. 8.3). Furthermore, it was shown that within each of these classes, there is clearly a range of rates at which the markers are observed to change, which could be location dependent. These results indicate that warming a sample for a short period, for example, during sectioning and mounting, may perturb the markers observed, in particular, when human tissue samples retrieved from the hospital are used. To guard against misinterpreting artifacts as real markers, a rigorous sample handling procedure should be employed. Approaches to prevent post-mortem degradation have been developed, for example, Denator AB has released the

Figure 8.3 Investigation of postmortem degradation in MALDI imaging MS. Optical and MALDI imaging MS analyses of 14- μm -thick mouse brain sections thaw-mounted onto ITO-coated slides. (a) Optical image of the mounted transcoronal sections. Strong white areas are Tipp-ExTM spots applied to the slide to coregister images. MALDI imaging MS analyses after 0, 0.5, 1, 1.75, 2.75, and 5.25 min for peptide peaks at m/z (b) 2608, (c) 2479, and (d) 6724 [31]. (See color insert.)

tissue stabilization system, Stabilizer T1 (Denator AB, Sweden), that rapidly inactivates enzymes by heat-induced denaturation and reduces postmortem degradation to improve the analysis of fresh and frozen tissue samples [48,49]. In an initial study, it was shown that posttranslational phosphorylations of analyzed proteins were stable and peptide extracts were devoid of abundant protein degradation fragments [48]. However, it should be noted that after treatment with the Stabilizer T1, the tissues could be more fragile and therefore difficult to handle. Goodwin *et al.* [49] have reported that changes to the tissue structure have also been found to have a negative effect on the quality of the imaging MS data, although they improved the stability. Given this information, it is imperative in clinical investigations that tissue collection protocols should be standardized to reduce the likelihood of sample-processing artifacts.

8.2.2 Sample Preparation

8.2.2.1 Wash. Washing the tissue sections before matrix deposition has proven to be useful to improve spectra quality by increasing the ion yields and the number of signals observed [50]. One of the main purposes of washing tissue sections is to remove salts, lipids, and excessive amounts of hemoglobin to enhance MALDI signals. The most common washing procedure consists of a 30-s wash in ice-cold 70% ethanol

Figure 8.4 Imaging MS analysis of serial sections cut from a clear cell renal cell carcinoma resection not washed or after washing with isopropanol, ethanol, acetic acid, or water. (a) Photomicrograph of a serial H&E stained section detailing the histology of the biopsy. Areas of normal kidney cortex, stroma, and tumor are visible. The area outlined was analyzed. (b) Photomicrograph of the sections used for IMS (ion mass spectrometry) after washing and automated matrix deposition. (c–h) Ion density maps for selected protein signals from the unwashed and washed sections [50]. HOAc, acetic acid; EtOH, ethanol; IPA, isopropanol. (See color insert.)

to remove salts and cell debris, followed by a 100% ethanol wash to dehydrate and fixate the tissue. For the removal of lipids, tissue sections can be washed in organic solvents, for example, chloroform or xylene [47]. In general, the washing conditions must be optimized for specific imaging MS experiments since different tissues may require different washes.

The washing strategy also influences which biomolecules can be analyzed. Seeley *et al.* [50] systematically explored the effects of several solvent combinations for washing tissue sections. Different molecules were detected after different washes, so combining different washes can create complementary data sets describing different molecules (Fig. 8.4) [50].

It is important to be aware of the fact that there is always a potential risk of molecular diffusion during any wash procedure. Tissue sections that are fixed can be kept for several days (up to seven) in a desiccator without noticeable degradation of MALDI spectra [45]. For small-molecule analysis, such as drugs and metabolites, the wash procedures are usually omitted as they may easily delocalize the analyte of interest.

Several methods have been reported that attempt to reverse formalin fixation to “retrieve” antigens. Antigen retrieval typically involves the application of a high temperature treatment along with the use of a buffer solution, in an effort to reverse protein cross-linking and return the tissue to its native state [40]. A schematic representation is given in Fig. 8.5. First, the paraffin is removed from the FFPE sections

Figure 8.5 Citric acid antigen retrieval (CAAR) method applied to imaging MS of FFPE tissue. In step 1, sections cut from the FFPE block are mounted onto an ITO-coated slide. Step 2 describes the antigen retrieval process. In step 3, the proteins are cleaved into proteolytic peptides and then extracted by the deposition of the MALDI matrix solution. Step 4 shows an example of the mass spectra and images that can be obtained [53].

using xylene (100%, twice for 20 min), followed by graded ethanol washes (100%, twice for 5 min, and successive washes of 95%, 80%, and 70% ethanol for 5 min). Then the tissue can be treated either by heating the section in a tris-EDTA buffer pH 9 at 95°C for 20 min [51,52] or by using a high temperature citric acid buffer [53].

The methylene bonds are difficult to break without destroying the peptide backbone. To solve this problem, endopeptidases such as trypsin are used directly on tissue sections to break down the protein network and retrieve the digested peptides that can additionally be used for protein identification [28].

Detection of intact proteins of a molecular mass >25 kDa has been much less successful than that of peptides and small proteins. One strategy to analyze those proteins is based on proteolytic digestion of the tissue's proteins followed by MALDI imaging MS of their tryptic peptides. In principle, this “bottom-up” strategy could enable proteins of any mass to be detected. The disadvantage is that all information regarding protein isoforms is lost. For example, in an on-tissue digestion investigation, the glucose-regulated protein 78 kDa (Grp78) was identified as being associated with human pancreatic adenocarcinoma (often referred to as *pancreatic cancer*). However, in a subsequent article, Scholz *et al.* [54] reported that several Grp78 isoforms in murine pancreas displayed significant changes solely due to postmortem protein degradation (F-test $p < 0.05$). It is much more difficult to control protein degradation in human tissue samples, and unless the tryptic peptides contain the specific posttranslational modifications of a protein's isoforms, information regarding protein isoforms is omitted.

Several strategies based on tissue washes have been developed to detect proteins of higher molecular mass. For example, a 28-kDa integral crystalline lens membrane protein could be detected after extensive washing with water to deplete highly abundant soluble proteins, followed by application of a matrix solution containing a high percentage of organic solvent [55]. This procedure would be difficult to apply as a general strategy as its success is based solely on extensive on-tissue protein purification of membrane proteins (which remain anchored to the insoluble membrane during the repeated water washes).

Another strategy has used a layered matrix preparation that enabled proteins in the 25- to 50-kDa range to be detected. It was found that Triton X-100, compatible with MS up to a concentration of 1%, aided in the detection of higher m/z proteins from tissue [56]. In short, a tissue section is placed on a drop of sinapinic acid (SA,

3,5-dimethoxy-4-hydroxycinnamic acid) matrix dissolved in 90% EtOH and 0.5% Triton X-100. Once dry, a drop of SA/xylene suspension was placed on top of the tissue section, followed by a layer of SA/90% EtOH and a layer of SA/50% acetonitrile (ACN). Franck *et al.* [57] developed a sample preparation strategy using the solvents 1,1,1,3,3,3-hexafluoro-2-propanol (HFIP) and 2,2,2-trifluoroethanol (TFE) for detection of high mass proteins with MALDI MS. Unfortunately, the very low viscosity and harsh chemical abrasiveness of HFIP and TFE make it difficult to apply this procedure with the automated sample preparation stations commonly used for MALDI imaging MS.

8.2.2.2 Matrix. The correct choice of matrix is crucial for a successful MALDI imaging MS experiment. The matrix, usually an aromatic acid, is used to absorb energy from the irradiating light source (usually a UV laser). Ablation of the matrix and gas-phase chemistry leads to the generation of gas-phase pseudomolecular ions [58]. Depending on the mass range analyzed and chemical properties of the molecules of interest, the matrix and solvent conditions should be chosen accordingly [36,45, 59–61].

The matrix α -cyano-4-hydroxycinnamic acid (CHCA) is commonly used for lower molecular weight masses (peptides <3000 Da), while SA is used for higher molecular masses (peptides >3000 Da and proteins). Phospholipid analysis typically involves either 2,5-dihydroxy benzoic acid (DHB) or 2,6-dihydroxyacetophenone (DHAP), and finally, CHCA and DHB are also often used for pharmaceuticals [62,63]. Ionic matrices, composed of a binary mixture of the matrix and a base (e.g., CHCA with aniline or *N*, *N*-dimethylaniline), have been reported to provide increased sensitivity and higher resistance to vacuum sublation [47]. The matrix 9-aminoacridine (9-AA) is used for the analysis of acidic metabolites and glycerophospholipids [64,65]. A summary of different matrices is given in Table 8.1.

The goal of the matrix solution is to effectively dissolve the analyte of interest and thus extract it from the tissue. The matrix solution typically consists of an organic solvent such as ACN or methanol, water, the matrix, and trifluoroacetic acid (TFA). The solvent composition, the matrix concentration, and the TFA concentration have all been shown to affect the protein profile obtained from a tissue [32]. It is for this reason that the matrix solution needs to be optimized for each application and then carefully and reproducibly applied to the tissue in order to obtain images that accurately represent the distribution of the molecules of interest within the tissue [32].

8.2.2.3 Matrix Application. MALDI MS requires the presence of matrix crystals. Imaging MS has been used to investigate the distribution of analytes within matrix crystals and has indicated a partial segregation within and between the crystals [66].

TABLE 8.1 A Summary of Matrices used in MALDI Imaging MS Experiments

Abbreviation	Chemical Name	Application
DHB	2,5-Dihydroxybenzoic acid	Lipids, peptides, carbohydrates
CHCA	α -Cyano-4-hydroxycinnamic acid	Peptides
SA	Sinapinic acid	Proteins
DHAP	2,6-Dihydroxyacetophenone	Lipids
PA	Picolinic acid	Oligonucleotides
9-AA	9-Aminoacridine	Metabolites

To avoid such artifacts, the matrix crystals need to be significantly smaller than the pixel size of the image. For imaging MS of peptides and proteins, the most common application, the analyte molecules need to be incorporated into the growing matrix crystals for high sensitivity analyses. In general, larger crystals have extracted more analyte from the tissue, leading to higher signals, but generate lower spatial resolution images. Smaller crystals maintain high spatial fidelity, enabling higher spatial resolution images to be obtained, but contain less extracted analyte and are thus associated with lower sensitivity.

Initial imaging MS experiments used a manual TLC (thin-layer chromatography) sprayer to apply a uniform matrix layer onto the tissue, and this remains one of the first methods used by new groups entering the field because of its low cost. However, it is generally associated with low reproducibility and the use of one of the commercially available automated systems is strongly recommended. These devices are based on either microspotting or spray deposition. The microspotters sequentially deposit 100- to 200-pL droplets of matrix solution according to a predefined array, whereas the sprayers deposit sequential layers of small droplets over the sample.

The important factors to consider are how does the deposition method affect extraction of the tissues' peptides and proteins? and does the deposition method influence matrix crystallization? Sequential deposition of tens of 100- to 200-pL-sized droplets, such that each position of the array is sampled using nanoliter-sized droplets of matrix solution, has been found to be highly effective at dissolving peptides and proteins in the tissue and incorporating them into the matrix crystals. For efficient extraction, the spray devices need to apply a sufficiently "wet" layer of matrix onto the tissue, but care must be taken to avoid depositing too many droplets onto the tissue, as flooding causes lateral migration. Several instruments have been developed to apply the matrix, for example, the ImagePrep device (Bruker, Germany) and the TM Sprayer (Leap Technologies, USA). The ImagePrep device attempts to prevent flooding and control matrix deposition by using an optical sensor to monitor the sample's wetness as well as the thickness of the matrix layer. Alternatively, the TM Sprayer uses a heated spray to ensure more rapid solvent evaporation. Using these commercial spray devices or a laboratory-built system to deposit multiple layers of matrix solution (incorporating multiple steps of peptide and protein extraction, redissolution, and recrystallization) a uniform layer of peptide/protein-doped matrix crystals can be obtained. Following matrix coating, samples maybe coated with a thin layer of metal such as gold to avoid sample charging and thereby increase the detected signals [39,40].

Several solvent-free matrix dry-coating methods have been developed for small-molecule analysis. Matrix sublimation can produce an even layer of small crystals across the tissue section [67]. The deposition can be readily controlled with time, temperature, and pressure settings and is highly reproducible from one sample to the next. This technique eliminates the potential for analyte migration during solution-based matrix application and produces very small crystals that are necessary for high spatial resolution measurements. However, the dry-coating approach is not suitable for peptide or protein analysis because these compounds need to be incorporated into the matrix crystals.

For the detection of lipids on tissue sections, a 20- μm sieve has also been used to deposit finely ground matrix onto tissue. The lipid signals obtained were comparable to those from spray-coated sections, producing identical localization patterns even with this simpler and faster sample preparation [68]. This approach was found to yield highly

reproducible results, eliminating much of the variance caused by operator differences and making it an attractive alternative to solvent-based methods. A similar method uses a ball-mill device to press the matrix through a metal mesh. The mesh (20 μm) produces 1- to 12- μm crystals (DHB, CHCA matrices) in 1 min, as determined by optical microscopy, permitting fast uniform matrix coverage. Even 1- to 5- μm sized crystals could be obtained using a 3- μm mesh [69].

8.2.3 The Experiment

8.2.3.1 The Spatial Resolution. The spatial resolution of an imaging MS experiment determines the size of the spatial features that can be resolved. The resolution is dependent on the sample preparation, signal intensity per pixel, the capabilities of the instrument (laser spot on target), and the distance between raster points. The laser spot size is dependent on the ion source, the focusing optics, and the geometry of the source. The spatial resolution desired is an important factor in determining the method of matrix application.

Imaging by using an array of small discrete droplets, deposited using an automated spotting device, limits sample migration to within the diameter of the matrix droplet, typically $\approx 150\ \mu\text{m}$. An array of such spots, with a 200- μm pitch, would be referred to as having a spatial resolution of 200 μm .

Recently, McDonnell *et al.* [70] indicated the protein concentration range accessible for MALDI imaging MS (Table 8.2). The table shows the amount of a specific protein in each pixel as a function of spatial resolution, tissue thickness, and protein concentration. Assuming a detection limit of 1 attomol (10^{-18} mol), a 10- μm pixel is the highest spatial resolution achievable for a 1- μM peptide present in a 10- μm -thick tissue section. At smaller pixel sizes, there is simply insufficient peptide/protein available to detect it using current MALDI strategies. In practice, the achievable resolution will be less because the efficiency of protein extraction, ionization, and detection is lower than 100%. Without significant improvements in sensitivity, high spatial resolution analysis will be limited to more abundant species that ionize well, such as lipids or peptides in endocrine tissues [70]. For example Rompp *et al.* [71] have reported high mass resolution and high spatial resolution (around 5 μm) of lipids and peptides in pituitary tissue.

The spatial resolution limitations highlighted here refer to the amount of protein present in a voxel and thus would also apply to a profiling workflow utilizing laser-capture microdissection, protein extraction, trypsin digestion, and LC-MS/MS. MALDI analysis of tissues can generate mass spectra containing hundreds of distinct peptide and protein peaks from a single $150 \times 150\text{-}\mu\text{m}$ pixel. Assuming an average cell size of 20 μm , this corresponds to < 60 cells. This is much smaller than the samples typically analyzed in a proteomics workflow using protein extraction and LC-MS/MS analysis and is a testament to the successful on-tissue fractionation of the ion, lipid, peptide, and protein components. Cornett *et al.* [12] have shown how the specificity and reproducibility of direct tissue profiling can be similar to those obtained using laser-capture microdissection but used far fewer cells.

8.2.3.2 Identification. In an imaging MS experiment, different proteins are distinguished and characterized by their intrinsic molecular mass; however, additional experiments are necessary to assign identities to these masses. In-source decay can be used to obtain N-terminal sequence information to identify proteins in a “top-down” strategy [72]. However, the lack of a precursor ion selection step can make

TABLE 8.2 Total Amount of a Specific Protein as a Function of Pixel Size, Tissue Thickness, and Protein Concentration^a. Combinations highlighted in green may be considered accessible in a modern MALDI ToF mass spectrometer

Concentration [M]	Tissue Thickness 10 μm					Tissue Thickness 2 μm

^aRef. 70.

in-source decay more difficult to apply to the analysis of complex samples such as a tissue section. Furthermore, the low charge state (the majority of MALDI-generated ions have unit charge) and large size of proteins make ion activation methods such as collision-activated dissociation inefficient. For these reasons, protein identification is normally performed using LC-MS/MS of tissue extracts or via on-tissue digestion protocols [39]. On-tissue digestion protocols deposit a trypsin solution in the same way as used for matrix application, thus forming proteolytic peptides of each protein while maintaining their original spatial distribution. Several groups have now demonstrated that on-tissue digestion combined with MALDI imaging MS can be used to identify and localize proteins through their tryptic peptides; among others, it has been applied to lung cancer [28], breast cancer [51], prostate cancer [73], and pancreatic adenocarcinoma [74]. Recently, N-terminal peptide derivatization strategies were shown to provide improved peptide identification by directing the fragmentation to provide a complete y -fragment series [75]. The increased complexity of the composition of the tissues following on-tissue digestion (every protein will form many different proteolytic fragments) means that on-tissue digestion and MALDI imaging MS analyses reporting new protein biomarkers will still need to be independently verified using additional means. Cazares *et al.* [73] recently used a combination of intact peptide and protein MALDI imaging MS, on-tissue digestion, and immunohistochemical staining (IHC) to demonstrate the localization of a new candidate protein biomarker in prostate cancer tumors. To identify lipid species, preliminary peak assignments can be obtained from the LIPID MAPS database (<http://lipidmaps.org>) and then further confirmed by performing MS/MS analysis. Neutral losses can provide headgroup information as well as identify the fatty acid groups of the lipids [76].

8.2.3.3 Mass Analyzers. Imaging MS has benefitted from recent technological innovations in the MS field. The most commonly used mass analyzers for imaging MS are ToF (time of flight) (linear, reflectron, and orthogonal), quadrupoles, hybrid instruments such as ToF/ToF or Q-ToF (quadrupole time of flight), ion-mobility ToF, and ion trap (IT) (QIT, Orbitrap, and FT-ICR (Fourier transform ion cyclotron resonance)). An overview of the commercial instruments that are used in the MALDI imaging MS field and their performance capabilities can be found on www.maldi-msi.org.

The majority of MALDI imaging MS is performed using ToF mass analyzers because they offer the combination of parallel detection of a broad mass range, high sensitivity, and high speed. The linear geometry is commonly used to image proteins because of the need for a high mass range, while the reflectron geometry is used to resolve and identify endogenous peptides and tryptic peptides [this geometry is more limited in mass range (<6 kDa)]. An orthogonal ToF enables the performance of the mass analyzer to be independent of the ionization step, thereby maintaining optimum performance of the mass analyzer throughout the tissue section [77]. The addition of ion mobility to a mass analyzer adds an additional, partially independent, separation dimension that distinguishes between ions on the basis of their gas-phase cross section and thereby further improves the separation of drugs, metabolites, lipids, and peptides [78]. The Fourier transform techniques, FT-ICR and Orbitrap, provide very high mass resolution capabilities, which can distinguish between isobaric species and thus is very useful for imaging lipids, drugs, and metabolites [79].

The detection sensitivity of the typical microchannel plate detector used in a ToF mass analyzer decreases at higher m/z because of the lower intrinsic ion-to-electron

conversion efficiency of slower moving ions and detection saturation [80]. When a ToF MS is equipped with a high mass detection system (CovalX, Switzerland), the detection of macromolecules, up to 1.2 MDa, with nanomolar sensitivity can be achieved. Recently, we showed that this detector with the sample preparations described above allowed the detection of large ions (>50 kDa) direct from tissue with higher sensitivity [81].

Hopfgartner *et al.* [82] have reported the use of a multiple reaction monitoring (MRM) instrument for MALDI imaging of pharmaceuticals and their metabolites in whole-body sections. MRM instruments can provide higher sensitivity than other mass analyzers, as well as very high speed, but require the mass and tandem mass spectra of each analyte of interest to be known before the experiment. MALDI MRM imaging is limited to the analysis of a small number of species owing to the finite number of laser shots that can be applied to a specific region of tissue and still yields biomolecular ions; nevertheless, the high sensitivity and high speed of the technique could make it a powerful tool for validation of candidate biomarkers in clinical tissue cohorts [83].

These examples demonstrate that high quality MALDI imaging MS experiments can be performed with most modern MALDI mass spectrometers, provided the samples have been prepared well. Sample preparation and the analysis of the resulting data are frequently the limiting factors in the workflow. Newly released MALDI mass spectrometers continue to offer improvements in speed, higher mass resolution, higher spatial resolution, and additional separation dimensions; all of which combine to generate larger data sets that need to be efficiently analyzed to take full advantage of the improved data quality and quantity.

8.2.3.4 Quantitation. Tissue-specific response curves have been used to quantify the amount of drug compounds in animal tissue. A dilution series of drug standards is applied on a set of tissues and the average response curve is determined [63]. For whole-body imaging MS experiments, it has been reported that the determination of relative response factors, for each organ in the whole-body section, could provide quantitative results in agreement with whole-body autoradiography [84]. This was performed by applying a uniform coating of the drug over an adjacent section and using the MALDI-generated ion signals to determine a relative response. Robust sample preparation methods of identical MALDI imaging MS experiments are crucial for quantifying MS images [63,85].

8.2.3.5 Integrating Histology and Imaging MS. A very important aspect of imaging MS analysis of tissue is to correlate the MS images with the morphological structures shown in histological images. Since the introduction of ITO glass slides, which enabled staining and imaging MS of the same tissue section [86], it is now a more common procedure to H&E stain the tissues after imaging MS analysis. After the measurement, the matrix is removed by washing the sections in 70% methanol twice for 30 s, followed by a standard H&E staining protocol. The optical image of the stained sections can then be coregistered with the MS image. The pathologist can annotate areas of particular interest, enabling a direct comparative analysis of the biomolecular signatures obtained from the specific histology features. Such histology-defined analyses have already led to the identification of several novel biomarkers, for example, in human brain tumors [11,23,27,28,73,87].

There are stains available, such as cresyl violet, Terry's polychrome, methylene blue, nuclear fast red, and toluidine blue, that are MS compatible with a minimal risk of protein delocalization [86]. These nuclear stainings can be of great help in providing higher accuracy for the imaging MS by focusing on specific morphological regions of interest. This technique can also be used in laser-capture microdissection to allow capture and direct analysis of specific cells of interest. Cornett *et al.* [12] have used histology-directed profiling to record the biomolecular profiles of different cell types.

8.2.3.6 Data Analysis. The analysis of imaging MS data can be separated into three distinct steps, namely, data preprocessing, statistical analysis, and visualization. Figure 8.6 shows a schematic representation of the data acquisition, data processing, and correlation strategies, which can be used [88]. First, the mass spectra are processed to reduce random noise (mass spectral smoothing), remove the nonspecific background signal prevalent in MALDI-MS spectra from tissue (background subtraction), correct for inhomogeneities in the matrix coverage (total-ion-count (TIC) normalization), and finally, align every pixel's mass spectrum onto a common m/z scale (mass spectral alignment). It has been shown how each of these steps can significantly improve the qualitative and quantitative information obtained from imaging MS experiments [88].

The statistical analysis performed on imaging MS data sets is largely determined by the goal of the experiment. MALDI imaging MS generates large and highly dimensional data sets that can describe the distributions of hundreds of peptide and protein signals. A comparative analysis of the different cell types in a tumor, as defined by histology, can be used to identify biomarker peptides and proteins specific to each cell type or to find peptide and protein profiles (incorporating multiple peptides and proteins)

Figure 8.6 Data processing and analysis workflow. The mass spectra are processed by removing the background signal, alignment of each pixel's m/z scale, normalization to each pixel's TIC, and finally peak selection. The reduced data from peak selection can then be subject to statistical analysis in order to identify specific features that discriminate between two (or more) specified classes, biomarker discovery, or to classify tissue based on their biomolecular content [88].

that discriminate between the different cell types. Such supervised, histology-defined classification of tissues has been performed using several different tools, including linear discriminant analysis [26], genetic algorithms [23], and support vector machines [23,28]. Groseclose *et al.* [28] used MALDI imaging MS to analyze a tissue microarray containing 112 needle-core biopsies from lung tumors diagnosed as adenocarcinoma and squamous cell carcinoma. A support vector machine classifier based on 73 tryptic peptides enabled regions marked as adenocarcinoma by a pathologist to be classified with an accuracy of 97.9% (140/143 spectra) and squamous cell carcinoma with an accuracy of 98.6% (141/143 spectra).

These classification studies are based on the prior histological annotation of the tissue. One of the potential advantages of MALDI imaging MS is that it can define a tissue based on its peptide and protein signature and thereby identify regions that display a molecular signature associated with a tumor but which have not yet undergone morphological transformation. For example, MALDI imaging MS analysis (supported by LC-MS) found colorectal-carcinoma-related proteins in histologically benign polyps, from which the authors inferred that these apparently benign polyps could have malignant potential [89]; recently, Willems *et al.* [90] demonstrated that imaging MS could reveal the intratumor heterogeneity of intermediate-grade myxoid fibrosarcoma tumors (which showed the same nodal structure in multiple patient samples).

A variety of data-analysis tools have been applied to examine the innate correlations within MALDI imaging MS data sets [26]. The most common, principal component analysis (PCA), is an unsupervised multivariate technique that maximizes the variance (spread) in the data to identify the peptides or proteins that are responsible for the largest variation in the data set [91]. The result is a series of orthogonal principal components (PCs) that describe, in descending order, the maximum variance in the data set, the next maximum variance (orthogonal to PC1), and so on. PCA is adept at finding the major variances within the data sets but will only reveal the molecular distributions of interest if the peptides and proteins have sufficient signal to noise (for their distributions to be described in earlier PC's than the noise). One of the tools beginning to establish itself in MALDI imaging MS is hierarchical cluster analysis [27]. This technique groups the pixels according to a hierarchical ordering of the similarity of their spectra. The resulting dendrogram displays the hierarchy and provides a simple tool to investigate the relationships between the pixels and thus to navigate the spatial variation of the tissue's peptide and protein profiles.

An imaging MS analysis creates a mass spectrum for every pixel of the image, each of which contains a multitude of peaks that describe the mass and intensity of specific biomolecules. These rich multiplex analyses generate very large data sets, which has limited most analysis of the innate variation in the biomolecular content of the tissue to a small numbers of tissues. Recently, McDonnell *et al.* [92] developed automated feature detection and extraction algorithms for imaging MS data sets that can effectively distill each pixel's mass spectral data into the features of interest and thereby reduce the data load by $\times 100$ –1000.

Finally, the visualization of 2D and 3D imaging MS data, whether the distribution of a single species or the results of a statistical analysis, is typically achieved using false color images. It is recommended that the user limits the number of channels (masses or results of data analysis) to a maximum of three. Three channels can be effectively communicated using RGB scales and clearly display overlapping regions in another color. A number of software packages are available to generate images from data

generated in an imaging MS experiment, for example, BioMap, Fleximaging, Axima2 Analyze, and Image Quest.

8.2.4 Novel Approaches—Targeted Analysis, Tissue Stretch, and Automation

Several methods have been developed that provide new variations to the imaging mass technique.

8.2.4.1 Targeted Imaging MS. This technique has been developed to enhance the specificity of the analysis. Functionalized antibodies carry a photocleavable reporter group that, can be detected by MALDI MS. The antibodies interact with an antigen of interest, and the localization of this antigen can be determined by analyzing the photocleavable probe. Two different methods have been developed: TagMass [71] and Targeted multiplex MS IMaging (TAMSIM) [93,94]. The TagMass procedure is based on specific MALDI imaging of proteins using a probe labeled with a photocleavable linker attached to a small peptide. The small peptide acts as the reporter molecule detected in the mass spectrometer and thus is used to image the distribution of the antigen. TAMSIM uses small, intrinsically ionic molecules as the reporters, for enhanced sensitivity. Different reporter molecules can be designed, allowing multiple markers to be tagged (Fig. 8.7) [93,94].

The tissue is incubated with the functionalized antibodies, up to three different tags have been reported in a single assay, without the risk of mutual quenching that can

Figure 8.7 TAMSIM: mass spectrometry analysis of mass-tag conjugated antibodies. Primary antibodies are incubated with the tissue section to bind with the antigen in the tissue. Secondary antibodies that each carries a specific mass tag are specifically attached to each primary antibody. The slide containing the tissue is then introduced into the mass spectrometer, where the pulsed UV laser of the MALDI ion sources cleaves the mass tags from their antibodies and releases them into the gas phase. The m/z values of the mass tags, provided by the mass spectrometer, differentiate between the different mass tags and thus provide antigen specificity. Spatially correlated analysis enables the distribution of each antigen in the tissue [93]. (See color insert.)

occur in fluorescence imaging. After irradiation of the tissue with laser, the reporter molecules are released from the antibodies and detected in the mass analyzer. Using labeled oligonucleotide and antibody probes, Lemaire *et al.* [95] have demonstrated how TagMass can be used to record the distribution of proenkephalin mRNA and a 180-kDa membrane protein. Recently, Thierry *et al.* [93,94] used TAMSIM to localize synaptophysin, chromogranin, insulin, calcitonin, and somatostatin in pancreatic neuroendocrine cells and the cancer markers PS100 and HMB45 in human lymph node and liver invaded by metastatic melanoma. Some of these proteins are below the detection threshold in a standard imaging MS experiment. Moreover targeted imaging MS can be applied to both frozen and FFPE tissue sections.

8.2.4.2 Tissue Stretch. In this method, a tissue section is placed onto an array of glass beads embedded in a parafilm membrane [96]. By stretching the membrane, the tissue section is fragmented into small individual pieces ($\sim 40\mu\text{m}$ in size) that can be individually prepared for MALDI-MS analysis. The physical separation between beads prevents analyte redistribution during matrix application and thus allows larger matrix droplets to be applied, thus enabling longer analyte extraction periods and increased sensitivity. This sample preparation has also been found to reduce the presence of alkali metal adducts [96]. This technology has been made more practical by the development of automated image reconstruction algorithms [97].

8.2.4.3 Automation. The low throughput of imaging MS has been one of the bottlenecks in investigating the clinical potential of using the multiplex molecular images as a novel molecular histological technique. Recently, an automated setup, consisting of a controlled environment sample storage chamber, a sample loading robot, and a MALDI-ToF/ToF MS, all controlled by a single user interface, was developed [98]. This approach in combination with the new high speed ToF/ToF instruments such as the AB Sciex ToF/ToF 5800, the ultrafleXtreme ToF/ToF from Bruker Daltonics, and the AB Sciex FlashQuant Triple Quad will provide the robustness and increased throughput for high throughput analyses.

8.3 APPLICATIONS

8.3.1 Oncology

Imaging MS can contribute significantly to cancer research as a tool to help diagnose tumors and provide indicators for the susceptibility to recurrence and progression. It can also be used as a discovery tool to detect biomarkers that are specific for early-stage tumor formation. MALDI imaging MS has already demonstrated its ability to distinguish cancerous tissue, differentiate between tumor types and tumor grades, and to locate protein biomarkers. Recently, an extensive review on imaging MS in cancer research was published by McDonnell *et al.* [70].

8.3.1.1 Brain Tumors. Meningiomas can be classified into three major grades: benign (grade I), atypical (grade II), and malignant (grade III). MALDI-MS profiling and imaging experiments of brain tumor tissues have shown how direct tissue analysis can locate gliomas as well as distinguish between the different tumor types,

grades, and subclasses [9,13,16,86,99,100]. For example, the protein thymosin β 4 was found to be primarily located in the proliferating head of the tumor, whereas the protein S100A4 was found localized in the tumor core [16].

Chaurand *et al.* [101] have shown how the levels of the calcium-binding protein S100B (and independently verified using IHC) can be used to distinguish high grade and low grade glioma. MALDI profiling MS has even revealed protein profiles that are correlated with tumor histology and patient survival [17]. Statistical analysis of the MALDI-MS profiles from 108 glioma patients, or the subset corresponding to 57 patients diagnosed with grade IV malignant gliomas, could identify protein profiles associated with shorter-term or longer-term survival.

To further develop imaging MS for clinical applications and to develop a reference database for predictive classification of brain tumors, Agar *et al.* [102] set up a study to evaluate predictive classification of brain tumors using imaging MS. A preliminary classifier based on a support vector machine model was able to distinguish between meningioma image spectra from the nontumor brain and gliomas and thus to enable class imaging of surgical tissue. It was demonstrated that the development of the classifier was very sensitive to data preparation parameters such as recalibration and the peak picking algorithm. Similar conclusions have been previously reported for clinical profiling experiments [103]. The performance of a classification algorithm is sensitive to systematic but nonconstant variations in the data due to differential sample processing, mass analysis methods, or data-processing routines. Consequently, it is crucial for clinical applications that standardized protocols are followed.

Three-dimensional MALDI imaging [19,104] has also been applied to brain tumors, specifically 3D imaging coregistered with *in vivo* magnetic resonance imaging (MRI) [105,106]. The integration of MALDI imaging MS can help establish the molecular phenotypes associated with the anatomical features detected with MRI and may help to assess if these changes in molecular phenotype occur before anatomical transformation [89]. The distribution of the astrocytic phosphoprotein Pea15, a protein previously determined to be elevated in grade III gliomas [17], is shown in Fig. 8.8, volume rendered against the corresponding *in vivo* MRI data. Good agreement could be obtained between the areas highlighted by MRI and areas with high Pea15 content. Figure 8.8b shows a comparison of 2D overlays of the MALDI imaging MS data and different MRI coefficients, as well as the results of a region-of-interest (ROI) analysis comparing regions inside and outside the tumor (in the cortex). It can be seen that both MRI and MALDI imaging MS can distinguish the tumor. The enhanced T_1 (longitudinal relaxation time weighted), diminished T_2 (transverse relaxation time weighted), and diminished ADC (apparent diffusion coefficient) signals observed in the MRI scans may be explained by differences in cell density, water, and protein content.

8.3.1.2 Breast Cancer. Direct MALDI analysis of mouse mammary tumor virus/HER2 transgenic mouse has revealed protein profiles that appear to predict the antitumor action of molecular therapies [13]. When treated with the erbB receptor inhibitors OSI-774 and Herceptin, inhibition of proliferation and induction of apoptosis and tumor reduction were predicted by a >80% reduction in thymosin β 4 and ubiquitin. The effects were time and dose dependent and confirmed by a MALDI imaging MS analysis, in which the spatial distributions of the proteins were inversely correlated with that of the small-molecule inhibitor.

Figure 8.8 Intermodal imaging. (a) Coregistered MALDI imaging MS and magnetic resonance imaging data from a whole mouse head. (Top) Corresponding slices from coregistered blockface, T_{1w} , T_{2w} , and diffusion weighted volumes, rendered in normalized grayscale (0 is black, 1 is white). (Bottom) The same slice with the MALDI imaging MS distribution of the protein Pea 15, a biomarker for grade III glioma, overlaid. (b) Results of a ROI analysis for manually selected normal and tumor tissue [106]. (See color insert.)

Knowledge of estrogen receptor (ER), progesterone receptor (PR), and, more recently, growth factor receptor HER2/neu (ERBB2) status has been critical in the evolution of modern targeted therapy and remains essential for making informed therapeutic decisions. Recently, it was demonstrated that a multiplex assay of the mRNA of these three proteins provided significantly improved diagnostic capabilities and could provide the personal “theranostic test” to guide therapy selection [107]. Rauser *et al.* [108] have demonstrated that MALDI imaging MS may determine HER2 status directly from patient tissues. MALDI imaging MS analysis of 48 breast cancer tissue samples revealed specific peptide and protein expression changes associated with HER2 status, which could classify tissues with 83% sensitivity, 92% specificity, and an overall accuracy of 89%. The cysteine-rich intestinal protein 1 was identified as one of the proteins strongly correlated with HER2 overexpression and demonstrates how MALDI imaging MS may help develop new tissue diagnostic procedures.

MALDI MS has been used to investigate the heterogeneous nature of protein expression in breast cancer tissues [50,105]. The profiling and MALDI imaging results shown in Fig. 8.9a revealed how the different regions of a breast cancer tissue section can

Figure 8.9 MALDI profiling versus imaging MS of human breast cancer tissue. (a) H&E stained tissue, and localized areas selected according to cell type. (b) MALDI-MS profiles obtained from cell types indicated in (a). (c) Histologically annotated H&E stained tissue section. (d) MALDI imaging MS analysis reveals distributions of specific proteins throughout the heterogeneous tissue section [105]. DCIS, ductal carcinoma *in situ*; IMC, invasive mammary cancer. (See color insert.)

generate different protein profiles. The images indicate that the individual proteins have quite heterogeneous spatial distributions but do not appear to follow the histologically annotated regions. Figure 8.9b shows the distributions of three proteins that are clearly associated with the different regions of the breast carcinoma tissue: histone H2A displays its highest abundance in the regions of the tissue histologically annotated as ductal carcinoma *in situ*, calgizzarin in invasive carcinoma, and thymosin $\beta 4$ in stroma [105].

MALDI imaging MS analysis has also been performed on FFPE breast cancer tissues using in-tissue digestion protocols [51,109] or targeted imaging of a known candidate biomarker protein [110]. Instead of endeavoring to find new biomarker profiles, Seuma *et al.* [110] used Au/Ag-tagged antibodies and the quantitative elemental imaging technique, laser ablation inductively coupled plasma MS, to quantitatively image known candidate biomarkers. The technique displayed good reproducibility and quantification, with limits of detection of ≈ 50 fmol for both Au- and Ag-tagged antibodies. The advantage of such targeted approaches is that they can exploit the findings of the large number of serum/plasma-profiling studies that have been undertaken in recent years.

A recent systematic review on the reproducibility of MS-based serum profiling for diagnosis of breast cancer revealed that despite substantial differences in experimental design, experimental conditions, data analysis, and even analytical reproducibility, a common set of discriminating and reproducible peaks could be found, indicating the presence of breast cancer [111]. The targeted imaging of these corroborated proteins in tissue microarrays could be performed using tagged antibody strategies.

8.3.1.3 Lung Cancer. Direct tissue analysis using MALDI profiling MS has been shown to be effective for accurately classifying and predicting histological groups as well as survival in resected non-small-cell lung cancer [112]. From a data set consisting of more than 1600 distinct protein peaks, differentially expressed peaks were found that could classify lung cancer histologies, distinguish primary tumors from metastases to the lung from other sites, and classify nodal involvement. A subset of the proteins, consisting of just 15 distinct protein peaks, was found that could distinguish between

patients with resected non-small-cell lung cancer and had poor prognosis (median survival 6 months, $n = 25$) and those who had good prognosis (median survival 33 months, $n = 41$, $p < 0.0001$). The above profiling study was performed by comparing the protein signatures from 1-mm regions of tissues from 79 lung tumors and 14 normal lung tissues; consequently, each profile effectively averages the signals from the highly heterogeneous tissue in each sample area (tumor regions chosen for analysis contained a tumor cellularity $>70\%$ [112]). The same group recently used MALDI imaging MS to analyze a small lung cancer tissue microarray containing 112 needle-core biopsies. An H&E stained section of the tissue microarray was analyzed by a pathologist using light microscopy and the cancer, noncancer, and normal regions were demarcated in each needle biopsy. This annotated tissue section was then aligned with an adjacent tissue section, which was then used for in-tissue digestion MALDI imaging MS. A subset of the needle biopsies was then used as a training set, in which the origin of each mass spectrum was annotated with the histologist's diagnosis (Fig. 8.10a). Even though the data sets included tryptic peptides that were found to be located in just a subset of each specific class [28], a support vector machine based classifier using 73 tryptic peptide peaks could classify the regions in the test samples (thus not included in the training set) marked as adenocarcinoma by a pathologist, with an accuracy of 97.9% (140/143 spectra), and squamous cell carcinoma, with an accuracy of 98.6% (141/143 spectra) (Fig. 8.10b).

8.3.1.4 Ovarian Cancer. Fournier and coworkers have reported an in-depth investigation for ovarian cancer candidate protein biomarkers using MALDI profiling of tissue extracts and MALDI imaging MS, which showed that the Reg-alpha fragment of the 11S proteasome activator complex is a new candidate protein biomarker. The candidate biomarker was identified by LC fractionation of the proteins from tissue extracts and determination of the appropriate fraction using MALDI profiling, followed by tryptic digestion and LC-MS/MS of the proteins in the fraction of interest. The results of the MALDI imaging MS investigation were then compared with IHC analysis using the anti-Reg-alpha C-terminal antibody and targeted MALDI imaging by using a primary antibody directed against the C-terminal part of human Reg-alpha and a secondary antibody modified with a photocleavable linker and a reporter peptide for MALDI-MS detection. Further analysis of the MALDI imaging data sets has demonstrated that hierarchical cluster analysis is highly effective in distinguishing the different regions of the tissue [113]. Liu *et al.* [114] used imaging MS to investigate the elevation of sulfatides in ovarian cancer in combination with transcriptomic and lipidomic approaches. In Fig. 8.11, pseudocolor ion images of sulfatides in ovarian carcinoma tissue are shown; sulfatides were only detected in the ovarian epithelial carcinoma and not in normal ovarian tissue (data not shown) [114]. Previous studies have shown that sulfatides are elevated in many types of cancer, including ovarian cancers, on the basis of colorimetric assay, which might have cross-reacted with other lipids (such as cardiolipin, phosphatidylserine, and phosphatidylinositol (PI)) [115]. Microarray mRNA data using a sphingolipid pathway map indicated that epithelial ovarian cancer cells might have elevated sulfatides, which was confirmed by LC ESI-MS/MS.

8.3.1.5 Prostate Cancer. Schwamborn *et al.* [23] have analyzed prostate cancer tissues using MALDI imaging MS to search for new and reliable candidate protein biomarkers. After the MALDI imaging MS experiment, the remaining matrix was

Figure 8.10 Classification of a lung cancer tissue microarray using MALDI imaging MS. (a) Optical image of an H&E stained section of the microarray and pathological diagnosis. (b) For training the diagnostic classifier, each spectrum is grouped based on the histological region from which it was acquired. (c) MALDI-imaging-MS-based classification of four biopsies compared to the diagnosis based on histology [28]. NSCLC, non-small-cell lung cancer. (See color insert.)

removed by incubating the slides twice in methanol (100%, at room temperature for 5 min) and once in acetone (100%, at room temperature for 5 min). The tissues were then H&E stained and a histological analysis performed. A support vector machine model was then built using histologically defined regions of interest (normal and cancerous areas). A false color image was created indicating those areas determined to be cancerous and compared with the results of a pathohistological analysis of the H&E stained section [23]. It was found that both regions could be distinguished with an overall cross-validation of 88% and a sensitivity and specificity of 85.21% and 90.74%, respectively, using 22 peptide and protein peaks [23]. The same data set, analyzed using just five peaks and a genetic algorithm, provided an overall cross-validation, sensitivity, and specificity of 77%, 70%, and 84%, respectively [23].

Figure 8.11 Visualization of the localization of sulfatides in ovarian carcinoma using MALDI imaging MS. (a) H&E stained thin section of an ovarian carcinoma and normal tissue. Distinctive morphological features have been outlined and superimposed on the (b–d) mass spectrometry images to aid in comparison. (b–d) Pseudocolor ion images of the ions at m/z (b) 778.6, (c) 888.6, and (d) 890.6 [114]. (See color insert.)

Cazares *et al.* recently reported a larger-scale MALDI imaging MS investigation of prostate cancer that led to the detection of a candidate biomarker. A discovery set of 11 cancer-containing tissues and 10 benign tissues was examined and a single peptide ion at m/z 4355 was found that could discriminate prostate cancer from normal tissue. This finding was then verified on a separate validation set of 54 tissue sections (23 tumor and 31 benign sections). This peptide was then identified as a fragment of mitogen-activated protein kinase/extracellular signal-regulated kinase kinase 2 (MEKK2) by tandem MS analysis of tissue lysates. On-tissue digestion MALDI imaging MS detected multiple tryptic peptides of the candidate biomarker, which were colocalized in prostate cancer tumors but not in benign or normal tissue, and immunohistochemical staining of MEKK2 showed increased expression in the tumor. This clinical study highlights the potential of MALDI imaging MS to significantly contribute to patient diagnosis and to identify new candidate biomarkers: in this case, MALDI imaging MS provided the first demonstration of MEKK2 overexpression in prostate tumors and its potential correlation with cancer stage/grade [73,116].

Chaurand *et al.* [10] compared normal mouse prostates with prostate tumors derived from genetically engineered mice (LPB-Tag mouse model for prostate cancer) by MALDI profiling and imaging MS to identify proteins common to normal prostatic morphogenesis and tumorigenesis. They showed that some secreted proteins were absent in tumors, indicating that expression of these differentiated proteins is decreased

or lost during tumor cell proliferation. Cyclophilin A (CypA), a protein found in other cancers, was detected with differential α N-terminal acetylation. Immunohistochemistry and Western blot analysis demonstrated the presence of CypA both in mouse prostate tumors and in human benign prostatic hyperplasia and prostate adenocarcinoma tissue sections, although the posttranslational modifications could not be discriminated by those techniques (in contrast to the MALDI imaging MS).

8.3.1.6 Tumors of the Gastrointestinal Tract. Following the prostate cancer analysis and the lung cancer tissue microarray analysis shown in Fig. 8.10, Dijidja *et al.* [117] recently demonstrated that MALDI imaging MS could be used to classify a pancreatic cancer tissue microarray and identified a number of proteins that appear to discriminate between different tumor classes. Figure 8.12 shows the distribution of some of the observed peptide signals within the tissue microarray sections. These peptides were identified as actin, periostin, hemoglobin α -chain, and histone 2A. Figure 8.13 displays the distribution of ion signals at m/z 944, 1032, and 1477 identified as histone 2A, histone H3, and type I collagen, respectively, which were found mainly in the tumor region. Figure 8.13d–f shows the H&E staining images of the section, which correspond with the MS images. All these analyses are based on tissue sections previously annotated by a trained pathologist. Although it is good practice to first test a new imaging method against established pathological analysis, such an

(e,f) The $\times 10$ magnification images acquired from tumor regions 1 and 2, showing tumor cells [117]. (See color insert.)

analysis will not highlight molecular differences that occur before the emergence of pathological entities.

A recent study combining MALDI imaging MS and LC-MS identified colorectal-carcinoma-related proteins in *histologically benign* polyps [89]. Examination of multiple benign polyps with MALDI imaging MS revealed colorectal-carcinoma-related proteins in the transition zone between the polyp and normal peripheral tissue, the area of greatest neovascularity and growth. This raised the concern that although a pathologist reporting no tumor in the normal tissue is correct, histology alone could underestimate the extent of preneoplastic changes (already reflected in different peptide/protein expression profiles detected by MALDI imaging MS) and progression of the lesion toward malignancy [89].

The ability to detect changes in disease-associated protein expression before their histological transformation is one of the main advantages of the nontargeted nature of the technique and arguably crucial to identify potential early-stage biomarkers. A new diagnostic method for separating benign from malignant colon polyps, based on histopathology in combination with MALDI imaging MS, may provide physicians with a more accurate diagnosis. The MALDI imaging MS measurements could also include candidate biomarkers spanning multiple molecular classes; for example, Shimma *et al.* [118] have reported that the lipids from a human colon cancer liver metastasis tissue sample clearly differentiate the cancerous regions of the tissue from the normal regions.

Gradual changes in expression levels of candidate biomarker proteins, changes in the relative levels of different proteins [15], and candidate biomarker proteins that are represented by weaker peaks in the mass spectrum require advanced data-analysis

Figure 8.14 MALDI imaging MS analysis of pancreatic adenocarcinoma, insulinoma, and healthy tissue. Hierarchical cluster analysis of (a) the pancreatic adenocarcinoma data set reveals (b) the substructure in the tissue. (c) Hierarchical cluster analysis of the combined data sets distinguishes the adenocarcinoma, insulinoma, and healthy tissues as well as the substructure in the subsequent branches [70]. (See color insert.)

tools to identify or confirm the different molecular signatures associated with the different regions of the tissue. This is especially true if the goal of an experiment is to identify different regions of tissue, based on their molecular content, independent of histological analysis (e.g., to identify molecular changes that occur before histological transformation).

The hierarchical cluster analysis of pancreatic ductal adenocarcinoma shown in Fig. 8.14 clearly reveals the spatiochemical substructure of the tissue, including an area bordering the tumor core that was verified in the original MALDI imaging MS data [70]. Furthermore, it was shown that the same analysis, independent of prior histological annotation, could differentiate between healthy pancreas, ductal adenocarcinoma, and insulinoma tissue *and* indicate the different regions of each tissue.

Deininger *et al.* [27] have used hierarchical cluster analysis to highlight the different features in nonneoplastic stomach mucosa and gastric cancer tissues. After demonstrating that each histological region could be distinguished solely on the basis of their different peptide and protein profiles (thereby demonstrating the technique's capability to reproduce histological features), it was postulated that MALDI imaging MS may be able to detect phenotypic differences invisible to classical histological techniques (Section 8.3.1.7). This study was performed on a small number of surgical gastric cancer samples. Kim *et al.* [119] performed a prospective clinical study to evaluate the feasibility of using MALDI imaging MS on frozen endoscopic biopsy samples for gastric cancer from 63 gastric cancer patients and 43 healthy volunteers. Half of the samples were used to develop a classification model and were validated using the other half. It was found that both regions could be distinguished with high predictive values

(positive and negative predictive values for cancer, 96.8% and 91.3%, respectively; sensitivity 93.8%; and specificity, 95.5%) using 73 peptide and protein peaks. Signals that were overexpressed in tumors were identified as α -defensin, α -defensin/2, calgranulin A, and calgranulin/B. Furthermore, they could distinguish early stage from more advanced-stage tumors.

8.3.1.7 Intratumor Heterogeneity. One of the foremost concerns in clinical oncology and pathology is ensuring complete tumor removal [120]. Local recurrence of cancer occurs quite often, despite microscopically confirmed negative surgical resection margins, and is likely related to the presence of abnormal, fully neoplastic or preneoplastic cells adjacent to the tumor that cannot be recognized by conventional light microscopy [121]. Tumor margins can be studied by antibody-based approaches or by nuclear staining procedures, which are limited to visualization of cellular morphology [122]. Identification of proteins that define the molecular microenvironment of the neoplastic process may become an important part of the evaluation of cancer tissue, potentially helping guide surgical resection procedures. MALDI imaging MS can significantly improve the assessment of microenvironment at the molecular level and thereby not only facilitate a better understanding of tumor invasion but also provide potential markers to aid in histological assessments that help ensure complete tumor removal. Caldwell and coworkers [121,123] used this technique to reveal that changes in protein content associated with a fibrous histiocytoma can extend far into adjacent histologically normal tissue. Kang *et al.* [124] reported how MALDI imaging MS could be used to identify proteins upregulated in tumor interface zones, the region between tumors and normal tissues where epithelial–mesenchymal transition occurs. It was proposed that these proteins maybe more effective prognostic biomarkers (than proteins that are upregulated within the tumor core). Plastin 2 and peroxiredoxin 1 were identified, and independent validation of their upregulation in the interface zones of ovarian cancer was performed using fluorescence microscopy.

More recently, Oppenheimer *et al.* [29] performed an in-depth investigation of tumor interface zones of renal cell carcinoma (RCC) and revealed that normal tissue adjacent to the tumor expresses many of the molecular characteristics of the tumor. They studied the correlation of the molecular changes in the margin-normal tissue with tumor aggressiveness. Mass spectra were acquired from the tissue containing tumor and the attached normal tissue, which allowed the mapping of proteins in tumor and adjacent normal tissue. The optical image of an H&E stained section was used to define the tumor border (Fig. 8.15a). A total of 40 significant features (m/z values) were plotted for 25 patients. Most samples expressed protein patterns exemplified by line “D” in Fig. 8.15b, where features are underexpressed in the tumor and the margin as compared to the nontumor tissue. The characteristics monitored were the point at which the maximum rate of change occurred and the point at which the feature amplitude began to plateau. There was not a clear correlation between the pathological diagnosis and the distance of compromised tissue beyond the histological tumor border. For the m/z features noted, expression patterns in most samples followed the aforementioned pattern illustrated in Fig. 8.15b. There was a small group of samples in which margin trends could not be assessed [29].

The imaging MS study of gastric cancer referred to above also provided the first indication that imaging MS may help reveal heterogeneity within tumors. Hierarchical

Figure 8.15 MALDI imaging MS analysis of tumor margins. (a) Optical image of tumor and adjacent normal tissue on a MALDI plate with regions of interest marked. (b) Optical image of a corresponding H&E stained section marked by a pathologist. (c) The observed patterns of the molecular features traversing the histological tumor margin. Lines A and C represent features that begin changing at the histological margin, while lines B and D represent features that change after the histological margin [29]. (See color insert.)

cluster analysis of an imaging data set revealed detailed clustering within the tumor that did not correspond to histologically distinct regions. The same data-analysis tool was recently used by Willems *et al.* [90] to demonstrate that intermediate-grade myxofibrosarcoma, a soft tissue tumor, possessed distinct areas with high-grade-like and low-grade-like character. To test if the regions could be further subdivided, on the basis of their biochemical signatures, and if the same intratumor heterogeneity is present in multiple tissues, six different localized regions of interest were selected in a single tissue sample and a support vector machine classification model was created. Application of this model to multiple intermediate-grade myxofibrosarcoma patient samples revealed that many intermediate-grade tissues exhibited significant biochemical intratumor heterogeneity. Furthermore, the results indicate that the areas previously highlighted as low-grade-like and high-grade-like consist of multiple nodules with different protein signatures. Low grade myxofibrosarcoma is microscopically characterized by a multinodular growth pattern [125]. The biomolecular heterogeneity might be due to metabolic and epigenetic differences in the tumor, though, strong evidence indicates that intratumor heterogeneity also arises from genetically distinct clones within the tumor [126,127]. Myxofibrosarcoma is characterized by nonspecific cytogenetic aberrations that increase with grade. It is thought that the tumors progress through multiple nodules, one of which becomes more dominant and progresses toward high grade myxofibrosarcoma (as has been shown in other neoplasms) [128–130]. Most human malignancies originate from a single cell but display intratumor heterogeneity by the time of diagnosis.

8.3.2 Degeneration—Neurological, Muscular, and Ocular

Molecular images of different neuropeptides have been reported, some of which were validated using immunohistochemistry [131]. Besides molecular images of peptides and proteins, different classes of lipids have also been imaged [132–138].

Wisztoski *et al.* [60] have reviewed the application of imaging MS in nervous tissues of both vertebrates and invertebrates with a focus on recent studies of neurodegenerative diseases. Langstrom *et al.* [139] have reviewed *in vitro* imaging techniques as a complement to *in vivo* positron-emission tomography (PET) and single photon emission computed tomography (SPECT) imaging in neurodegenerative diseases.

In rat brain frozen tissue sections treated with 6-hydroxydopamine, a neurotoxin commonly used to lesion dopaminergic pathways and generate experimental models for Parkinson disease, it was shown that transelongation factor 1, hexokinase, and neurofilament-M were downregulated as previously shown [140], whereas peroxidoredoxin 6, F1 ATPase, and α -enolase were upregulated [20,40]. Stauber *et al.* [40] identified three new putative biomarkers for Parkinson disease using FFPE 6-hydroxydopamine-treated rat brain tissues. Protein identification was obtained using MALDI MS direct profiling with nanoLC-nanoESI-IT MS. They confirmed that hexokinase and neurofilament-M proteins were downregulated, whereas the collapsing proteins response mediator 1 and 2, peroxidoredoxin 6, F1 ATPase, ubiquitin, and α -enolase were upregulated.

AD is a progressive neurodegenerative disorder characterized by the gradual onset of dementia. The pathological hallmarks of the disease are amyloid β plaques, neurofibrillary tangles, synaptic loss, and reactive gliosis. The localization, characterization, and quantification of amyloid β peptides have been studied in APP23 mouse brains [21,141]. Amyloid β peptides 1–40 and 1–42 were the most abundant amyloid peptides in those brain areas, which were identified by MS/MS analysis.

Scraper, a protein which is localized at the synapses in neurons, is an ubiquitin E3 ligase that is involved in the decomposition of Rab3-interacting molecule 1, an important regulator of synaptic plasticity, and thus regulates synaptic transmission. The *Scraper* knockout mouse brain showed two types of neurodegenerative pathologies, spongiform neurodegeneration and shrinkage of neuronal cells. In a comparison of a WT and SCR-KO mouse brains, both imaging MS and 2DE analysis detected altered molecules. There were several differences in information obtained from each procedure [142]; however, the additional value of imaging MS was that it showed the localization of several altered molecular species in the SCR-KO mouse brain spanning several molecular classes, including lipids, peptides, and small molecular weight proteins (<10 kDa), which are difficult to detect with 2DE analysis.

The *mdx* mouse is a model of Duchenne muscular dystrophy (DMD). Duchenne is a neuromuscular inherited, autosomal recessive disease. In DMD patients and *mdx* mice, modifications of the lipid composition of dystrophin-deficient muscle analyzed by radiolabeling, gas chromatography, or thin-layer chromatography [143] as well as oxidative damage [144] have been demonstrated. The most important difficulty remains the fact that in muscle biopsies, the muscle fibers are mixed with adipose and conjunctive tissues, which can be difficult to separate. The degeneration/regeneration process in muscles of *mdx* mouse was studied using MALDI-ToF profiling and cluster ToF secondary ion mass spectrometry (SIMS) imaging. Three regions in the *mdx* mouse legs could be distinguished: a severely damaged region, a second degenerating region (oxidative stress and deregulation of the PI cycle), and a third stable region [145,146]. ToF-SIMS imaging has the major advantage, over alternative methods, of allowing direct and simultaneous collection of mass spectra and ion images.

The determination of molecular composition and individual compound localization on a tissue section, at micrometer scale and without the need of any prior sample

treatment, makes the analysis easier, more straightforward, and the closest possible to physiological conditions.

Mass spectra revealed differences in the distribution of fatty acids, phospholipids, diglycerides (DGs), and triglycerides (TGs). Vitamin E and PIs were found to concentrate within the cells, whereas intact phosphocholines accumulated over the most damaged areas of the dystrophic muscles, together with cholesterol and sphingomyelin species. Fatty acyl chain composition varied depending on the region, allowing estimation of the local damage extent [147]. Recently, Benabdellah *et al.* showed inversion of the PC34:2/PC34:1 intensity ratio between destructed areas (from dystrophic muscle) and control areas (healthy muscle and structured areas from dystrophic muscle), which was interpreted as evidence of restoration of membrane lipid composition after treatment of *mdx* mice with molsidomine [64,65].

MALDI tissue profiling and imaging of proteins in ocular lenses have been developed to investigate the distribution of lens proteins [55,148–151]. Because of the lack of protein turnover, lens proteins undergo various age-related posttranslational modifications that include truncation, deamidation, glycation, and phosphorylation. The modifications accumulate over the lifetime of mammalian species and possibly contribute to lens opacification and cataractogenesis by inducing aggregation of lens proteins. While immunolabeling can be used to investigate several protein distribution patterns, its ability to simultaneously detect more than four specific antibody probes is limited principally due to the small number of discrete recording channels available. Furthermore standard immunohistochemical approaches can be challenged by the lack of specific antibodies to phosphorylated forms, the inability to detect specific truncation products, and the large number of individual experiments required to obtain this information. Molecular images showed the spatial distribution of the integral lens protein aquaporin, and its truncated products, namely, MP20, opsin, and α -crystallin, and their modified forms in one single experiment [55,148–151]. α A-crystallin was extensively degraded in the lens core; α B-crystalline degradation was limited and phosphorylation was most abundant in the middle cortex [55,148–150]. The results were validated by identification of the proteins and the modification by additional reverse-phase liquid chromatography of soluble extracts from specific tissue regions followed by tandem MS [150]. In addition, the regional distribution of lipids in porcine lens were mapped. The intraocular lens contains high levels of both cholesterol and sphingolipids, which are believed to be functionally important for normal lens physiology. Seven lens sphingomyelins and two ceramide-1-phosphates were imaged and further assigned by imaging FT-ICR MS. Glycosylated sphingolipids or sphingolipid breakdown products were not detected. Surprisingly, neither the cholesterol ion nor its dehydrated fragment ion could be detected by imaging MS, although the cholesterol molecules could be detected by SIMS and desorption electrospray ionization (DESI). This is probably due to the strong integration of cholesterol molecules in the lens [152].

8.3.3 Drugs, Tracers, and Metabolites

8.3.3.1 Drugs and Tracers. In 2003, Reyzer *et al.* [153] demonstrated that imaging MS could be used to trace the distribution of pharmaceuticals in various organs. It has rapidly developed into highly effective technique for imaging the distribution of small organic molecules, both exogenous drugs and endogenous metabolic intermediates

[154]. The advantage of this technique for metabolite imaging is that it does not require any labels or specific probes; it is a nontargeted method, and thereby many types of molecules can be analyzed simultaneously. Moreover, the parent drug and its metabolites can be distinguished [155,156], which is not possible with autoradiography or fluorescence imaging. Rohner *et al.* [157] reviewed MALDI imaging MS and described imaging work being carried out at Novartis. From the same group, there was also a report describing some of the practical aspects of obtaining imaging MS data for drug and metabolite distributions [85].

The mass range containing most drugs and metabolites can be densely populated with many ions of similar mass. Consequently, many experiments have used MS/MS to increase specificity. The increased resolving power of ion-mobility MS or FT-ICR MS enables drugs and metabolites to be distinguished using MS [132,136,155,156, 158–160]. MALDI imaging MS has attracted great interest from drug development companies. In recent years, numerous studies have been reported, where imaging MS has been used to monitor the distribution of an administered drug and its metabolites, for example, antitumor drugs (vinblastine, imatinib, banoxantrone, oxaliplatin, and diazepam) [155,156, 160–162], antipsychotics (olanzapine and clozapine) [48,119,121], antianxiety drugs and hypnotics (temazepam), treatment of chronic obstructive pulmonary disease (tiotropium) [63,163], HIV protease inhibitors [164], and an antifungal drug (ketoconazole)[62].

As described earlier, it is very important to avoid delocalization of the analyte and care must be taken when using MS to ensure there are no interfering peaks from the matrix or from endogenous compounds present in the tissue. Sample preparation procedures including the choice of matrix extraction solvents and detection method may need to be developed because of the range of structures, solubility, and physicochemical properties of drug compounds [165]. Several recent papers describe sample preparation protocols for drug imaging in which elimination of matrix-derived ions are developed such as the use of nanoparticle-based ionization [136,166], matrix-enhanced surface-assisted desorption/ionization [167], desorption/ionization on silicon [168], and nanostructure-initiator MS [169].

Imaging MS for low molecular weight compounds has been analyzed on ToF, IT, Q-ToF, IT-ToF, FT-ICR, and QqQLIT (a triple quadrupole in which the final quadrupole is a quadrupolar linear ion trap) mass analyzers [155,156]. Recent developments using MRM showed that images of a complete rat section could be accomplished with a 1000 Hz laser frequency and a rastering speed of about 18 mm/s, so a whole image of a drug compound distribution could be measured within 15 min [82].

Stoeckli *et al.* [85] and Hiesh *et al.* [84] showed that imaging MS provided detailed drug distribution images that are comparable to traditional whole-body autoradiography using radiolabeled compounds. Both methods showed high levels of a compound in several organs, while low levels in the blood were also detected. Autoradiography requires laborious and expensive synthesis and labeling of a tag with the risk of altering the pharmacological properties of the drug. Unlike autoradiography, imaging MS can distinguish the medicinally intact drugs from their metabolites. Khatib-Shahidi *et al.* [156] showed that in complete rat sections, the intact drug reached the target organ (the brain), whereas its metabolites were localized in the bladder (Fig. 8.16a).

Furthermore, the time course of the metabolism of parent drugs into demethylated and hydroxymethylated metabolites was visualized over the whole-body section (Fig. 8.16b). In this study, notable decreases of olanzapine were observed everywhere

Figure 8.16 MALDI imaging MS of the drug olanzapine and its metabolites in a whole rat sagittal tissue section (a) 2 h post dose and (b) 6 h post dose. (A) Optical images of tissue sections, in which the organs have been outlined with a dark gray dotted line. (B) MS/MS images of olanzapine (m/z 256). (C) MS/MS ion image of *N*-desmethyl metabolite (m/z 256). (D) MS/MS ion image of 2-hydroxymethyl metabolite (m/z 272). Scale bar = 1 cm [156]. (See color insert.)

in the body except the testis and bladder, while the metabolized compounds accumulated in the bladder. The differentiation of clozapine concentrations within the rat brain was confirmed using a fast HPLC/MS/MS method. Close examination of the distribution of drugs within specific organs can also be used to assess drug penetration. Bouslimani *et al.* [161] showed that the platinum antitumor drug oxaliplatin was localized exclusively in the kidney cortex, suggesting that it did not penetrate deep into the organ.

The spatiochemical information provided by imaging MS has also been used to investigate the distribution of pharmaceutical compounds in tablet formulations [170]. Tablets are compacted pharmaceutical dosage forms that contain active drug compounds and excipients. These results indicate that imaging MS can assist in the development of drug-delivery systems as well as in lead development. MALDI imaging MS was recently exploited to independently measure the distribution of MRI contrast-enhancement agents in both frozen and paraformaldehyde-fixed mouse livers, which were independently validated by both an *in vivo* MRI and an *ex vivo* inductively coupled plasma atomic emission spectroscopy [171]. The development of targeted MRI contrast-enhancement agents is one of the key tools being developed for early, non-invasive detection of disease biomarkers, and imaging MS could provide an independent measurement of its distribution in tissue to ensure its colocalization with the target biomarker.

8.3.3.2 Endogenous Metabolites. Endogenous metabolites can give insight into metabolic changes linked to drug administration or disease. Among the endogenous

Figure 8.17 Lipid imaging mass spectrometry of high and low grade myxoid liposarcoma (MLS) reveals differential lipid profiles, and the spatial distributions show the localization of specific lipids in one tumor grade. The lipids were identified using tandem mass spectrometry. The experimental mass, the assignment, and the mass accuracy of the assignments are provided alongside the image [90]. *Matrix clusters. (See color insert.)

metabolites, simple lipids (e.g., cholesterol, acylglycerides, and fatty acids) and complex lipids (e.g., glycerophospholipids and glycosphingolipids), as well as aminoacids, flavonoids, and oligosaccharides, have been investigated and reviewed by Sugiura and Setou [154].

Lipid analysis of myxoid liposarcomas by imaging MS revealed differences between low and high grade tumors [90]. Low and high grade tumors each contain specifically expressed lipids whose images clearly reveal their localization to one grade (Fig. 8.17). These lipids were then identified using MS/MS and the LIPID MAPS database. The spectra from high grade tumors revealed higher levels of phosphocholines. Phosphocholines are commonly detected by MALDI and are thought to be derived from (cell) membranes. The higher levels of these lipids in high grade tumors are consistent with the higher cellularity of higher grade tumors [172]. Low grade myxoid liposarcoma contained additional peaks because of triacylglycerols. Active PPAR γ signaling promotes adipocytic differentiation in preadipocytes and is active in myxoid liposarcoma cells [173]. The data suggest decreased PPAR γ -regulated fatty acid synthesis in myxoid liposarcoma upon increase in grade, histologically reflected in a diminished adipocytic phenotype, and consistent with recent work that established that PPAR γ inactivation by the FUS/DDIT3 liposarcoma-specific fusion protein is required for liposarcoma development [174].

The molecular ion distribution of intact lipids directly from single neuroblastoma cells was studied using matrix-enhanced (ME) SIMS. The ME-SIMS spectrum of these cell surfaces showed several lipid species in the mass range between m/z 700 and 900, ceramide, diacylglycerol species between m/z 500 and 700, and organic fragments in the lower mass range. High cholesterol signal intensity was found at the border of the cells, the plasma membrane, compared to the center of the cells, corresponding to the nuclei [175].

Background matrix peaks can be abundant in the low m/z range and can severely complicate metabolite imaging MS experiments. In order to improve the analysis of metabolites using imaging MS, different matrices have been investigated; 9-AA has

been reported as a highly promising matrix for metabolite analysis. No matrix signal was detected in the m/z range between 300 and 1000, the mass range where metabolite ion peaks are expected to be detected [64]. Furthermore, 13 primary metabolites at m/z values 323 (uridine monophosphate), 328 (cyclic adenosine monophosphate), 339 (fructose-1,6-biphosphate), 346 (adenosine monophosphate), 362 (guanosine monophosphate), 403 (uridine diphosphate), 426 (adenosine diphosphate), 442 (guanosine diphosphate), 506 (adenosine triphosphate), 522 (guanosine triphosphate), 558 (ADP-ribose), 565 (UDP-glucose), and 606 (UDP-GlcNAc) were observed, whereas none of them was detected using other matrices [64]. Identifications were made by tandem MS/MS comparing fragment fingerprints obtained from the tissue section and from standard samples. The distributions of those primary metabolites with a sensitivity of attomoles per pixel on rat brain sections were shown. As primary metabolites are known to be biomarkers of several brain disorders, imaging MS can be useful to study those metabolic changes [64].

8.4 PERSPECTIVES

Since its introduction in the late 1990s, MALDI imaging MS technology has made tremendous advances. Imaging MS is now used to investigate many different molecular classes, including peptides, proteins, lipids, metabolites, and drugs. The potential application of MALDI imaging MS in neurodegenerative diseases, cancer, viral infections, and drug metabolism lies in its ability to generate profiles in a nontargeted manner. These abilities enable the technique to detect unexpected and *a priori* unknown changes in the protein content of the tissue, for example, the presence of colorectal carcinoma biomarkers in histologically benign tissue [89], and to describe the tissue by a spectrum of peptides and proteins. MALDI imaging MS can also be adapted to span multiple molecular classes using essentially the same technique but different sample preparation strategies (peptides, proteins, lipids [118], and metabolites [64]), and can be integrated with established *in vitro* and *in vivo* analyses, thus the scope for complementary analyses is open. To investigate this potential in the clinic, the application largely driving the field, the biomolecular signatures obtained from the supervised and unsupervised analysis of the tissues are beginning to be tested across the large number of samples typically included in clinical cohorts [73].

To date, the classification of tissues using MALDI imaging MS has been based on established histological analysis [23,28,73]. The mass spectra obtained from a set of histologically annotated tissue sections are used to create a classifier, which is then applied to other tissue sections to test its performance. The ability of MALDI imaging MS to reproduce established histological classification demonstrates its ability to acquire clinically relevant data and can be considered the necessary first step of any new diagnostic/prognostic tool. The identification of new candidate protein profile biomarkers based on MALDI imaging MS, independent of histological analysis and thus able to detect biochemical changes before the appearance of pathological entities, has been performed for a small number of tissue sections [27,87]. Arguably, the next step in the development of MALDI-imaging-MS-based biomarker discovery is the development of classifiers based on the simultaneous analysis of tissue arrays. Such high throughput analysis will exploit the recently announced high speed MALDI mass spectrometers and imaging MS automation [98].

MALDI imaging MS is a rapidly developing tool that has great potential for improved diagnostic/prognostic capabilities. Nevertheless, it will be most effective when implemented as part of a concerted effort utilizing a range of complementary techniques and expertise.

MALDI imaging MS on small molecules has opened a new frontier both in pharmaceutical and toxicological research and in the developmental phase of new drugs. The potential of this technique lies in its ability to visualize and distinguish the parent drug and its metabolites and is an attractive alternative for monitoring drug distribution within animal models, with much faster results and lower cost than the traditional whole-body autoradiography method [85,176]. The possibility to monitor in parallel multiple analytes, with high specificity and rapid acquisition, makes it a very promising tool for drug development. Furthermore, this technique can study in one analysis the ability of the compound of interest to reach the target organ, the drug penetration into the target organ, and the diffusion to undesirable organs [161]. It offers the possibility of not only examining and tracking drug metabolism in whole animal sections but also following polymer substrate degradation and drug release.

9.1 INTRODUCTION

Metabolite analysis is a demanding initiative for analytical technologies. It is estimated that between 4000 and 20,000 distinct metabolites are expressed in eukaryotic organisms, spanning between seven and nine orders of magnitude in concentration range [1,2], which necessitates highly sensitive and broad dynamic range analyses. This is particularly true when considering xenobiotic metabolites, in which all feasible biotransformations that an administered drug may undergo must also be considered. These may occur over a large dynamic range of possible concentrations, and depending on the dose administered, may require highly sensitive analytical techniques [3]. Metabolism is a dynamic process, requiring measurement strategies that provide high sample throughput and instrument duty cycle. A further challenge is that metabolites represent a diverse set of chemical classes possessing disparate polarities, such that there is no single extraction or separation technique that can handle most, much less all, metabolites present. Because of the shortcoming of current technologies, contemporary profiling strategies are necessarily focused on a relatively small number of known metabolites and thus are noncomprehensive. Nevertheless, targeted analysis and

low complexity metabolite profiling approaches have been highly successful in drug discovery and development [4,5].

Established bioanalytical methods for studying metabolites are predominately based on nuclear magnetic resonance (NMR) and mass spectrometry (MS). MS methods are widely used and are routinely combined with additional separations [e.g., gas chromatography (GC) and liquid chromatography (LC) before MS identification] to improve instrument sensitivity and dynamic range to detect lower abundance analytes. In parallel with advances in MS has been the development of postionization gas-phase separations based on ion mobility (IM) [6–8]. IM is a compartmentalized technology that offers a combined separation and analysis that is ca. four to six orders of magnitude faster than GC and LC, respectively [9]. Since gas-phase ionization is a prerequisite for both IM and MS, the two methods are commonly coupled into a single analysis technique referred to as *IM-MS*, which allows separations on the basis of two physical properties: IM (size) and ion mass (weight). IM-MS is still an emerging technology, and one major challenge associated with using IM-MS for metabolite profiling is the limited amount of validation that can be drawn from the literature. Another challenge is the limited orthogonality between IM and MS separation dimensions, since analyte size and mass are two closely correlated physical properties [10]. Nevertheless, the extremely high speeds of the separation (micro- to milliseconds) and the potential for enhancing existing MS methodologies offer great promise for IM-MS to become a complementary bioanalytical technique for dynamic metabolic and metabolomics analyses.

This chapter provides an overview of the IM technique and a review of the various analytical approaches that utilize IM for metabolomics. The coupling of IM and MS is discussed in light of the analytical advantages and the additional information gained in these two-dimensional analyses. In recent years, high resolution mass spectrometers have allowed for the determination of metabolite identity based on high mass accuracy measurements, which allow for the determination of metabolic transformations based on mass defect filtering, which is further enhanced in combination with IM. Tandem MS experiments (MS/MS) are important methods for elucidating analyte identity, and the common methods of operation are outlined. The addition of IM capabilities to MS instrumentation permits several useful combinations of tandem experiments (e.g., IM-MS/MS, MS/IM-MS, and MS-IM-MS/MS), which enhance the current commercial MS/MS capabilities; these are discussed in detail at the end of this chapter.

9.2 AN OVERVIEW OF ION MOBILITY TECHNIQUES

IM can be broadly defined as the *kinetic behavior* (velocity) of ions in a neutral gas. Differences in the velocity of two ions, even those isomeric in mass, can be used to differentiate the two ions experimentally. The analytical technique that utilizes the property of IM to separate ions is often called *IM spectrometry* to draw parallels with MS. Other names such as gas-phase electrophoresis [11] and plasma chromatography [12] have also been used. In terms of the technology, IM spectrometry closely resembles MS; however, the separation mechanism is very similar to chromatography, which can cause confusion if the fundamentals of the IM method are described from either (a spectrometric or chromatographic) perspective [13]. In this chapter, we refer to the analytical technique simply as IM and make important distinctions where necessary.

From a pedagogical perspective, all IM techniques can be conceptualized as a series of opposing vector forces: (i) the electric field force that directs ions across a defined region and (ii) the opposing force of ion–gas collisions that impedes this forward motion. In the simplest IM experiment, ions are pulled by an electric field through a chamber filled with a constant pressure of gas and disperse in time based on differences in their mobility. The number of ion–gas collisions is related to the size of the ion. Thus, for two ions of equal mass but different sizes, the smaller of the two will have a higher ionic mobility (velocity) and traverse the region the fastest, arriving on the other side of the region first. This kind of IM experiment is known as the *drift tube IM technique* and is the most commonly encountered IM method in the literature.

The term *ion mobility* does not refer to any single experimental method but it encompasses a family of different analytical techniques, all of which utilize the same basic concept of an ion's gas-phase mobility to generate an analytically useful separation. As with MS, IM techniques can be broadly divided into two categories: (i) temporally dispersive methods, which separate all ions in time but along the same spatial path, and (ii) spatially dispersive methods, which separate ions along different trajectories. The conceptual differences between temporal and spatial dispersion are depicted in Fig. 9.1. Temporally dispersive IM methods can obtain a complete IM spectrum in a single measurement cycle, while spatially dispersive IM techniques while spatially dispersive IM techniques transmit only a narrow IM range transmit only a narrow IM range of ions at a time. Members of the spatially dispersive IM category are considered scanning methods, which filter ions based on their mobilities and require that a parameter (typically a voltage) be scanned in order to generate the broadband spectrum. Table 9.1 contains a listing of several different IM methods along with their defining attributes. The distinction between any two IM techniques can be made by comparing the relative direction of the various field forces (electric field and gas flow) with respect to the motion of the ion. Note here that the ion motion will preferentially follow one of the forces such that the ion velocity vector is aligned with one of the force vectors. A listing of the analogous MS method for each IM technique is also provided in Table 9.1.

Figure 9.1 Conceptual schematic of the two types of separation schemes for ion-mobility techniques. (a) Temporally dispersive separation methods partition a pulse of ions into different mobility values along the same spatial trajectory. Ions of different mobilities arrive at different times during each measurement pulse. (b) Spatially dispersive separation methods partition a continuous beam of ions into different mobility values along different spatial trajectories, with each trajectory representing ions possessing common gas-phase mobilities.

The following sections describe each of the specific IM techniques in more detail. We start with a qualitative description of the drift tube IM method and use concepts discussed there as the foundation for understanding other IM techniques. These methods are initially discussed in the absence of MS; however, the IM techniques are framed as modular rather than as stand-alone or end detection technologies. Governing equations, although important for each technique, are avoided in this chapter in order to convey the qualitative operational principles clearly. The reader is directed toward specific references given in Table 9.1 if a more thorough understanding of each technique is sought.

9.2.1 Drift Tube Ion Mobility Spectrometry

The drift tube IM technique is the most familiar IM method and has been a commercial technology since the 1970s, although it has primarily been used as a stand-alone technology for chemical screening in security applications [24]. Drift tube instruments can operate at either ambient pressure (ca. 760 Torr) or reduced pressure (ca. 1–10 Torr), the latter more amenable to coupling with vacuum MS techniques. Ambient pressure drift tubes do not need bulky vacuum systems, and owing to the high gas number densities, the IM separation occurs in a relatively short distance, so these instruments are often preferred as low cost, portable chemical detectors. Reduced-pressure drift tubes are more costly and technically complex due to the added vacuum hardware, but they offer very high measurement precision and accuracy and are readily coupled to mass spectrometers. Complicating ion chemistry is often avoided at reduced pressures, where ions experience fewer interactions with trace gas impurities inherently present in the drift gases used. Reduced-pressure drift tubes are generally preferred in research applications where high quality ion measurements are desired, but one major disadvantage has traditionally been that these instruments were not readily available commercially. This situation has changed in the last five years or so as several commercial vendors have begun offering high performance drift tube IM-MS equipment.

The basic components and operational principle of the drift tube IM technique are depicted in Fig. 9.2a. A uniform electric field is defined along the length of a tube by a series of stacked ring electrodes. The tube is filled with an inert gas, usually helium or nitrogen, which is maintained at a constant pressure and low flow conditions. A pulse of ions is introduced at one end and allowed to drift down the length of the tube by the influence of the electric field via electrophoretic migration. During the ion's drift, it collides many times with the drift gas ($>10^4$ collisions at 1 Torr), which slows the ion's forward motion. The amount of time any given ion spends in the drift tube is directly related to the number of collisions it experiences, which in turn depends on its collision cross section or nominal gas-phase size and shape. This is analogous in principle to GC, where the less volatile (lower vapor pressure) analyte will spend more time in the column. The measured drift times in the IM experiment are essentially the same in principle as retention times measured in chromatography, but it is important to note that IM is not chromatography in the strictest sense, as there is no stationary phase (and thus no phase partitioning) but a constantly moving density of gas.

Because the electric field, gas pressure (number density), temperature, and tube length are (ideally) all kept constant in the drift tube IM experiment, the relationship between the measured ion drift time and the collision cross section is direct and can

Figure 9.2 The operation principles governing the four ion mobility techniques. (a) The drift tube ion-mobility method disperses ions of differing mobilities temporally along the same trajectory by utilizing a continuous declining potential across a gas-filled region. (b) The traveling wave ion-mobility method achieves temporally dispersive mobility separations using a traveling wave potential across a gas-filled region. (c) The high field asymmetric waveform ion-mobility method disperses ions spatially along different trajectories using an orthogonally applied asymmetric waveform as ions are entrained in a gas flow. (d) The differential mobility analyzer disperses ions spatially by mobility using a flow of gas and an orthogonally applied uniform electric field.

be determined from first principle kinetic equations [25]. The measurement of absolute gas-phase collision cross sections of ions is an important feature of the drift tube experiment. The interpretation of the collision cross section value is, however, not straightforward since effects such as neutral gas polarization can contribute to nonideal (inelastic) ion–gas interactions [26]. This is particularly significant for small molecules such as metabolites, where the analyte polarity can contribute to a more attractive ion–gas interaction (a “sticky” collision), which will make the collision cross section appear larger than the physical size of the gas-phase analyte ion. Thus, it is difficult to assign any physical meaning to the collision cross sections measured for small molecules in the IM experiment. For larger analyte ions, greater than about m/z 500, the size effects become the significant contributor to the measured drift times, and in this case, collision cross section is a close representation of the physical size and shape of the gas-phase ion. The use of nonpolar drift gases also improves the accuracy of the collision cross section measurement, which is why helium is often preferred in research drift tube instruments. One prevailing advantage of drift tube instruments over the other IM techniques described in this chapter is the very high resolving powers that

can be achieved (>200) [19], which makes drift tubes important IM instrumentation for core research and development.

9.2.2 Traveling Wave Ion Mobility Spectrometry

Traveling wave is a relatively new IM technique but has already shown great promise to become a routine method for chemical analysis. This is largely due to the rapid commercialization of the technology, which is now widely available integrated into a high end mass spectrometer platform [14]. The first commercial traveling wave instrument was released in 2006 (Synapt HDMS, Waters) and has since seen a major revision (Synapt G2, 2009), which has improved the IM resolving power by about a factor of 4 (currently ca. 40–50) and offers mass resolving powers of up to ca. 50,000. The traveling wave concept itself can be traced back to early accelerator physics applications [27] and early work with using radio frequency (RF) fields to determine ionic mobilities [28,29], but until recently, there have been no attempts made at translating this technology to separating ions by mobility on an analytical scale.

The basic components of the traveling wave IM device is shown in Fig. 9.2b and are essentially the same as what can be found in a drift tube IM instrument. The drift region consists of a stacked ring ion guide and is filled with a low static pressure (1–5 Torr) of nitrogen. The rings serve two purposes: (i) a sinusoidal RF potential is applied to confine ions to the center axis of the device to improve instrument sensitivity, while (ii) a pulsed voltage is applied on sets of rings and rapidly switched from one end of the device to the other to generate the traveling wave potential for IM separation. Ions that are introduced to the device in narrow pulses will be picked up by the wave and pushed down the length of the drift region where they experience many collisions with the nitrogen gas. Some ions experience more collisions with the drift gas and are pushed against the wave until they fall behind it and wait for the next wave to carry them forward again. The number of times any given ion will tumble behind the wave is directly related to its ionic mobility—larger ions are inherently more difficult to push forward than small ions. Thus, the device disperses ions based on their mobilities in much the same way as the drift tube experiment, although fundamentally this is achieved in a very different manner. Because the wave travels at a fixed velocity, only ions that fall behind the wave will separate—those ions that are pushed along by a single wave will arrive at the same drift time and result in no useful mobility separation. Factors such as the wave velocity and voltage amplitude must be tuned in order to obtain a good mobility separation. The current second-generation traveling wave instrument (Synapt G2) can achieve IM resolving powers of ca. 45 (authors' laboratory).

Because of the complex potentials utilized in the traveling wave IM instrument, there is no direct first principle correlation between measured drift times and collision cross sections. For those interested in obtaining structural information from the IM experiment, this is seen as a disadvantage when using the traveling wave IM technique, though, methods have been proposed. By preparing a calibration curve with standards of known collision cross section, structural values have been extracted using traveling wave IM. This method is limited to the range of the calibration curve, which typically limits this method to the analysis of a particular biomolecular class. Additionally, methods of dynamically changing the traveling wave velocity for the determination

of mobility have been presented as well, though, this method is not commercially available and not particularly feasible for complex sample analysis. However, there are two distinct advantages that traveling wave IM offer over traditional drift tube IM. First, the axially confining electric fields result in very little ion loss and thus very good analyte sensitivity. Second, the traveling wave device is much easier to couple to other instrumentation due to the fact that the potential at the start and exit of the device remains the same. In contrast, coupling instrumentation such as MS to a drift tube IM device requires either the front or back component be biased to a nonzero electric potential, increasing technical complexity. A third advantage might be that traveling wave instruments are becoming much more accessible to mainstream analytical research and will no doubt see some exciting applications in the near future, particularly in the area of drug research and discovery.

Both the drift tube and traveling wave IM techniques disperse ions temporally along the same space, which permits an entire broadband mobility spectrum to be generated in each experimental measurement cycle. This has the obvious advantage of allowing one to obtain data on several analyte peaks at the same time. One limitation of temporally dispersive approaches is that ions are introduced in pulses, requiring that each measurement be complete before another pulse is admitted (a duty cycle), which reduces the overall sample throughput of the technique. In some cases, it is desirable to only monitor a few select analyte signals continuously, and so the next two IM techniques discussed act as narrow bandpass mobility filters and are particularly well suited for analyte monitoring applications.

9.2.3 High Field Asymmetric Waveform Ion Mobility and Differential Mobility Spectrometry

Consider now a continuous stream of ions entrained in a gas flow that passes between two parallel plates (Fig. 9.2c). One plate is kept at a constant potential, usually ground, and on the other plate is applied an alternating (AC) voltage. This AC voltage is kept at the same average potential as the opposite plate but alternates between a short duration, high amplitude and a longer duration, low amplitude (an asymmetric waveform) (Fig. 9.2c). The total magnitude of each push/pull potential is the same, such that the ions experience the same average electric field for each cycle, but in opposite directions. If the mobility of the ion during the push cycle is the same as during the pull cycle, the ion's average displacement will be zero. However, the gas-phase mobility of an ion has an electric field dependence such that it changes between going from high field (ca. 20,000 V/cm) to low field (ca. 1000 V/cm) [30]. This results in a different net displacement of the ion when subjected to the short duration, high field wave cycle than when it experiences the longer duration, lower field wave cycle. Ultimately, this results in ions that are not balanced by the asymmetric waveform to be neutralized onto one of the plates. This device will transmit a narrow bandpass of ions whose high field and low field IM is exactly matched by the waveform. An additional compensation voltage is applied to either plate to allow the device to be scanned, thus filtering ions possessing different changes in high/low field ion mobilities.

Devices that utilize this principle of IM separation have been described by several names, the two most popular being high field asymmetric waveform ion-mobility spectrometry (FAIMS) and differential mobility spectrometry (DMS). In Table 9.1, we refer to both techniques as *differential high/low field IM*. Both terms describe the same

general technique with defining differences being in the geometry of the electrodes used and how ions are detected in stand-alone applications. FAIMS and DMS devices do not separate purely by IM but by the difference in high/low field IM (the first derivative), so the observed separations are often subtly different from those derived from the other IM methods. In many cases, these devices can resolve ion species that are difficult to separate by traditional IM methods, such as leucine and isoleucine [31]. Additionally, one can couple FAIMS or DMS with a temporally dispersive IM method (i.e., drift tube or traveling wave IM spectrometry) and achieve excellent orthogonality between the two separations [32], which is analogous in principle to two-dimensional GC using polar and nonpolar columns. FAIMS and DMS have been successfully used to separate a variety of small molecules and both technologies are commercially available as front-end separators for mass spectrometers (FAIMS, Thermo Scientific, and DMS, Sionex). Because these devices operate at or near ambient pressure, they are readily compatible with atmospheric pressure ionization sources.

The high/low field IM behavior and transition between differential behaviors are still poorly understood. Because there is no first principle correlation between the change in IM and the low field collision cross section, analyte size information is difficult to obtain with any accuracy using the differential high–low field IM technique. Gas-phase collision cross sections can be determined in differential high–low field IM through special energy loss experiments using triple quadrupole MS [33].

9.2.4 Differential Mobility Analyzer

Differential mobility analyzers (DMAs) are a special class of IM instruments used primarily for measuring the size of aerosol particles >5 nm in diameter. These instruments are not commonly used for small molecules due to high diffusive ion losses; however, the method is included here to complete the discussion of IM technologies. The reader may skip to the next section if more relevant discussion regarding IM techniques for metabolite analysis is preferred.

Building on the differential high/low field IM technique described in the previous section, consider now a similar experimental setup, whereby ions are entrained in a flowing gas and allowed to pass between two parallel plates as shown in Fig. 9.2d. Instead of an alternating voltage, a direct voltage is applied across the two plates creating a uniform electric potential gradient perpendicular to the ion transit. This will cause ions to migrate from one plate to the other as they are being pulled along by the gas flow. All ions of the same charge will experience the same force of the electric field, but because of differences in their ion mobilities, smaller ions will be displaced at a shorter distance than larger ions. This results in a spatial dispersion of ions based on their ionic mobilities. Practical designs of this type of transverse field IM instrument utilize small apertures or slits on the parallel plates, which are offset at some defined distance from one another, as depicted in Fig. 9.2d. Ions are introduced to the gas stream through one slit, and the voltage is tuned to allow ions with different mobilities to pass through the second slit, in much the same way as tuning the m/z of a magnetic sector MS instrument. With the exit slit design, the instrument operates in a scanning mode. The exit slit can also be replaced by an array detector, which allows for broadband IM spectrum to be measured [34]; however, this design cannot be coupled as a front end to MS (e.g., IM-MS).

These instruments are sometimes called *aspirator mobility analyzers* due to the aspiration effect of introducing ions into the gas stream. More commonly they are referred to as *differential mobility analyzer (DMA)* and by the trade name gas-phase electrophoretic molecular mobility analyzer (GEMMA), the latter now referred to as *macroIMS* (TSI Incorporated). The DMA nomenclature is oftentimes confused with the DMS technique described in the previous section, but it should be noted that these two IM techniques separate ions by two very distinct mechanisms, specifically the DMA differentiates ions based on aerodynamic ionic mobility (IM in the presence of a gas flow), whereas DMS exploits IM differences between high and low electric field conditions. DMA and GEMMA have been highly successful in measuring particle sizes down to the nanometer range [17]. Smaller ions are more difficult to transmit due to diffusive losses and the instrument performance is inherently tied to the size of the slits used—larger slits improve sensitivity at a cost of resolution and vice versa. Recent technological improvements show promise for extending the usable size range down to small molecular ions with high sensitivity and IM resolution [23].

As with drift tube IM instruments, DMA measurements can be used to determine the ion's effective size since there is a direct relationship between the experimental conditions (transmission voltage and gas flow rate) and the experimentally measured gas-phase IM. A hard sphere model is used to relate the measured IM value to an effective size. As mentioned previously, DMA instruments are currently limited to the analysis of relatively large ions (tens of nanometers or greater in diameter), requiring that effects such as surface roughness be accounted for in the size calculation [35]. Nonetheless, because the DMA experimental separation parameters (voltage, drift length, and gas flow) are well characterized, the resulting measurement precision of the DMA technique is high.

9.3 INTEGRATED ION MOBILITY–MASS SPECTROMETRY

All the IM methods described previously can operate as a stand-alone chemical analysis technology (i.e., an IM spectrometer). One shortcoming of IM analysis alone is that the measured ionic mobility is a relative property of the analyte and will change with respect to different experimental conditions (e.g., drift gas pressure, temperature, and composition). Consequently, confident analyte identification using IM spectrometry information alone (via the reduced mobility) relies on rigorous method validation and even then is subject to specific constraints on the system being studied [36–38]. In contrast, MS measures an inherent physical property of the analyte (mass or more specifically, the mass-to-charge ratio), which can be used for analyte identification purposes, as the property of ion mass is readily comparable across instrument platforms. MS and tandem MS methods are the cornerstone technology of many analyte characterization initiatives, a fact that is reflected in the numerous contributions to this volume. Owing to the requirement that the analyte be ionized, IM is particularly suited for coupling with MS. The first IM-MS instruments appeared in the 1960s in response to the need to better characterize the ion chemistry observed in drift tubes [39,40]. Bioanalytical drift tube mass spectrometers emerged in the 1990s owing to the development of soft ionization methods (MALDI and ESI (electrospray ionization), which are discussed in other chapters) [6]. IM-MS is now widely utilized and regarded as a technique in and of itself [41], much like the integration of LC to MS (LC-MS). Most

of the technical challenges associated with coupling the elevated pressure IM stage to a vacuum MS have been solved, largely due to parallel initiatives in improving the transfer efficiency of ions from atmospheric ionization sources to MS [42]. As mentioned previously, commercially available IM-MS instruments are now emerging and offer little to no compromise in performance as compared with the familiar MS platforms in which they are coupled. Thus, researchers familiar with existing commercial MS technologies will find that IM capabilities enhance existing methodologies built upon MS analysis.

9.3.1 Ion Mobility–Mass Spectrometry Instrumentation

Figure 9.3a illustrates the basic components of an IM-MS instrument. Sample introduction can include direct infusion, GC, or LC. Virtually every ionization source that has been used in MS has been coupled to an IM-MS instrument [41], including all the ionization techniques covered in this volume. Likewise, virtually every combination of IM and MS has been attempted. Temporally dispersive IM (drift tube and traveling wave) combined with temporally dispersive MS (time of flight, TOF) is a particularly useful combination since both techniques offer broadband analysis for each experimental cycle [43]. Another useful combination is coupling a scanning IM (e.g., FAIMS or DMS) to a scanning MS (an ion trap), which allows selective monitoring and analysis experiments [44]. Instruments based on bracketing an IM between two mass spectrometer stages (MS-IM-MS) have also been developed [45], allowing several useful stages of tandem ion experiment to be conducted [46]. We discuss various combinations of tandem IM/MS in the later sections. Commonality between all these instrument configurations is the back-end mass analysis, which provides a comprehensive characterization of the sample by mass or, specifically, the mass-to-charge ratio. For the purposes of this chapter, we focus primarily on IM-MS instruments that incorporate the first stage of mass selection and tandem capabilities with a high resolution mass spectrometer (the so-called high performance IM-MS, Fig. 9.3b). Although the literature defines high resolution mass spectrometers with a degree of disparity, we consider high

Figure 9.3 (a) A schematic of the basic components of an ion mobility–mass spectrometer. From left to right: sample is introduced, ionized, then separated first by ion mobility and then by mass, and finally, detected. (b) A “high performance” ion mobility–mass spectrometer can include a mass spectrometer before the ion-mobility spectrometer and several stages of ion activation located between each spectrometer component. Additionally, the spectrometers operate with high precision (resolving power) and sensitivity, enabling high quality measurements of mobility and mass to be made.

resolution as the ability to obtain part-per-million mass precision (e.g., 1000 ± 0.015 Da, or 20,000 resolving power) within the mass-to-charge range of interest.

9.3.2 Orthogonality and Peak Capacity in Ion Mobility–Mass Spectrometry Analyses

The observed mobility–mass correlation in IM-MS data limits the orthogonality of the two separations. Completely orthogonal measurements would distribute data throughout two-dimensional separation space with no correlation between the data sets, as each separation is contingent upon chemical or physical properties that are independent of one another [47]. In other words, data projected on a two-dimensional separation plot would occupy all the separations space, as illustrated conceptually in Fig. 9.4a, where analyte signals distribute themselves across the full two-dimensional area. This high orthogonality is often observed, for example, in 2D gel electrophoresis [48,49], where the two dimensions of separation are analyte mass and isoelectric point—two unrelated analyte parameters. The degree of orthogonality of IM-MS separations is low due to the correlation of mass and size [50]. This is apparent when considering an ion of increasing mass, which will inherently possess a larger volume and therefore occupy an established region of separations space, a mobility–mass correlation termed *conformational space* [51]. Low orthogonality inherently limits the peak capacity (ϕ) of the IM separation, which is the maximum number of resolvable peaks within the separation window, as illustrated in Fig. 9.4b for a hypothetical IM-MS spectrum [52]. Here, the

Figure 9.4 (a) A theoretical distribution of peaks (represented in black in grid space) in two-dimensional space for completely orthogonal separations. Each axis corresponds to a theoretical separation parameter. The high orthogonality allows for the occupancy of all two-dimensional space, thus having a peak capacity equivalent to the product of the two peak capacities. (b) Two separations with low orthogonality. The region of two-dimensional separations space that peaks occupy is limited to a fraction of all separations space. The region of analysis space is narrowed to that shown in the overlapping regions, for example. This limits peak capacity, as the total peak capacity is no longer the product of the two peak capacities, but a corrected value that is a fraction of the maximum. The gray areas are regions of separation space, in which no signal appears.

narrow distribution of data requires that the analysis window be narrowed accordingly, depicted with the dotted lines in Fig. 9.4b. Previous IM studies have reported a peak capacity of ~ 5 for the IM dimension alone, which is low when compared with other separation methods [10]. However, the strength of IM is that when combined with MS, the overall peak capacity of the MS dimension is increased multiplicatively (specifically, fivefold, for this example). As there is virtually no compromise in analytical performance when IM is added to MS, this represents a significant improvement in analytical performance. For example, IM-MS has recently demonstrated a peak capacity of 10^3 for metabolites in a single IM-MS spectrum, which is comparable to that of highly orthogonal methods, such as reverse phase LC-MS ($\phi = 1000\text{--}1500$, *Shewanella oneidensis* lysate) [53], two-dimensional GC-MS (GC $\times$ GC-MS, $\phi = 1200$, lean C57BL/6 mice spleen extract, $\phi = 1800$ human serum) [54,55], and capillary electrophoresis-MS (CE-MS, $\phi = 1692$, *Bacillus subtilis* extract) [56]. These examples represent general separation benchmarks for each analytical platform, and while useful for qualitative comparative purposes, it should be noted that the samples, conditions, and mass spectrometers are not consistent across each study.

9.3.3 Ion Mobility–Mass Spectrometry Analysis Speed

The main strength IM holds over conventional separations techniques is that it occurs post ionization, which means separations are performed entirely in the gas phase. This results in a separation that occurs on the order of hundreds of microseconds to milliseconds. As a result, thousands of IM spectra can be acquired each second. When compared with previously presented separation methods that are utilized before ionization (e.g., LC, CE, and GC), the time required for a mobility separation to occur is several orders of magnitude faster. An analysis speed comparison of several separation techniques is provided in Fig. 9.5. For a typical metabolomics study, high performance LC, two-dimensional GC, and CE separations occur on the order of minutes to hours. Additionally, GC separations often require analyte derivatization to promote volatility,

Figure 9.5 Speeds for separation techniques commonly applied to metabolite analysis. Note the logarithmic scaling on the abscissa.

TABLE 9.2 Several Single-Dimensional Separation Methods and the Parameters for Separation, Peak Capacity (ϕ), and Peak Production Rate (ϕ/s)

Separation Method (Single Dimension)	Separation Parameter	Peak Capacity (ϕ)	Signal Peak Production Rate (ϕ/s)	References
Capillary electrophoresis (CE)	Electrophoretic mobility	1000	0.5	62
Gas chromatography (GC)	Vapor pressure	75	6	63
Liquid chromatography (LC)	Hydrophobicity	60	0.06	64,65
Ultrahigh pressure LC		300	0.2	
1D slab gel electrophoresis	Isoelectric point, mass	100	0.03	66
Field-flow fractionation (FFF)	Hydrodynamic radius	10	0.005	66,67
Ion mobility (IM)	Gas-phase cross section	5	500	10

which adds multiple hours in addition to the separation [55,57–61]. While the orthogonality and peak capacity of IM-MS remains comparable to other two-dimensional methods, it is the high speed of IM-MS that affords a great analytical advantage in terms of the peak production rate, as illustrated in Table 9.2 [9].

In addition to the high data production rate of IM-MS, another key advantage of coupling time dispersive IM and MS is the complimentary nature of the timescales for each dimension of analysis. Because time dispersive IM separations (millisecond) occur two to three orders of magnitude slower than time dispersive MS (microsecond), hundreds of mass spectra can be acquired for each IM spectrum, which benefits the sampling resolution across the IM dimension [68]. This temporal sampling benefit is commonly exploited in LC-MS where each LC trace is sampled numerous times by the MS. One criticism of LC-MS has been that the immensely disparate timescales (six to eight orders of magnitude) ineffectively utilize the throughput of the mass spectrometer. IM readily bridges this time disparity between LC and MS, which has been demonstrated for the three-dimensional analysis of complex biological samples [69]. CE-IM-MS has also been demonstrated to improve the sensitivity of MS for low abundance analytes in complex biological samples [70]. Combining front-end separation techniques with IM-MS is still an emerging area that holds great promise for improving the chemical analysis for both contemporary and future applications.

9.3.4 Information Content of Ion Mobility–Mass Spectrometry Analyses

One favorable consequence of the data correlation between IM and mass is the potential for extracting additional information regarding specific analytes within the sample.

Figure 9.6 (a) Shown is a nanoelectrospray ionization–ion mobility–mass spectrum of a methanol extract of rat blood. Mass-to-charge ratio is depicted on the abscissa, with mobility drift time represented on the ordinate (ms). Peaks are false colored to illustrate relative abundance, with the scale displayed in the inset. Shown above the IM-MS plot is the corresponding mass spectrum for the entire sample. Regions corresponding to various mobility–mass correlation lines are highlighted and labeled, with the extracted mass spectra displayed in (b). Preliminary identifications are assigned based on conformational space occupation. (See color insert.)

This complimentary information can be used in a number of ways for more confident identification and characterization of analyte signals within the sample. Figure 9.6a contains a two-dimensional projection of IM-mass data for a nanoelectrosprayed sample of a methanol extract of rat blood. This data was obtained in <1 min in the authors' laboratory using a traveling wave IM-MS instrument. The spectrum displays m/z (Da) on the abscissa and drift time (ms) on the ordinate. The spectrum is false colored

(heat mapped) to represent relative signal abundances and is composed of almost exclusively singly charged ions due to the nano-ESI conditions utilized. Immediately obvious is the close correlation between the mobility and mass, which manifests as a clustering of data along a mobility–mass correlation line [71]. This results from the intuitive scaling of the analyte size with its weight. Figure 9.6b illustrates the advantage of selective interrogation of data corresponding to the mobility–mass correlation for lipids, peptides, and small molecules. The individual mass spectrum is extracted directly from the combined mobility–mass spectra (Fig. 9.6a). The result is the extraction of relevant analyte signals, based on the distillation of chemical noise, which greatly improves the amount of information that can be gleaned from the data. This strategy has recently been shown to be applicable to metabolite identification for the IM-MS analysis of human blood [72], rat lymph fluid [73], and *Escherichia coli* extracts [74].

One of the challenges of metabolite studies is the diverse representation of chemical species classified as metabolites. These include both large (e.g., peptides, lipids, and glycosides) and small (e.g., alkaloids, terpenes, and phenols) biomolecules, but traditionally focused on the latter because of the available technologies for small-molecule analysis (e.g., GC-MS). As described previously, the IM-MS analysis provides an advantageous dimension of information in the form of molecular class-specific mobility–mass correlation lines, which can be used for identification purposes and also for isolation and extraction of certain chemical signals. From a global analysis perspective, this has the advantage of interrogating a large amount of chemical data simultaneously, which is particularly advantageous for whole systems approaches [75]. As an example of the utility of IM-MS for whole systems studies, Fig. 9.7a depicts a mapping of ion collision cross section (IM) versus ion mass for a large sample

Figure 9.7 (a) The mass-to-charge values and calculated collision cross sections (in Å²) obtained using a drift tube ion mobility–mass spectrometer for 53 lipids, 610 peptides, 192 carbohydrates, and 96 oligonucleotides, illustrating the separation of biomolecular classes in two-dimensional space using IM-MS. (b) Logarithmic regression fits applied to the biomolecular class distributions in (a). *Source:* Adapted from Fenn LS, Kliman M, Mahsutt A, Zhao SR, McLean JA. *Anal Bioanal Chem* 2009;394:235. Fig. 9.1(a,b), with kind permission from Springer Science+Business Media. (See color insert.)

number ($n = 951$) representing four biomolecular chemical classes: lipids, carbohydrates, peptides, and nucleotides. Figure 9.7b contains logarithmic regression fits of the data sets in Fig. 9.7a and illustrates the average mobility–mass correlation for each biomolecular class. Note that the IM data normally projected as drift time has been converted to collision cross section (in $\text{\AA}^2$). What is immediately obvious is that the average mobility–mass correlation is different for each class, with notable disparity between peptides and carbohydrates. The data projections in Fig. 9.6 represent an initial attempt at mapping mobility–mass data space for a large data set representative of several molecular classes. The ultimate goal of such a project is to generate a reliable “atlas” of conformational space of biologically relevant molecules and apply this *a priori* knowledge toward an integrated “omics” approach [76].

9.4 TANDEM METHODS FOR ION MOBILITY–MASS SPECTROMETRY/MASS SPECTROMETRY

IM has so far been discussed with regard to the analytical merit of performing fast separation of mixtures and using the resulting separation to locate relevant chemical signals that may otherwise be disregarded in a single dimension of mass analysis, such as the case of structural isomers. While the identification of significant analyte signals (markers) in the spectrometric analysis is certainly important, it is more challenging to then assign these signals a chemical identity [77]. Tandem MS experiments (MS/MS) are a critical aspect of MS approaches to metabolite identification. MS/MS involves two mass separation steps with ion fragmentation occurring in between. The first MS is used to isolate one mass to charge, which is then subjected to a fragmentation step (most commonly through energetic gas collisions in a pressurized chamber), causing decomposition of the selected precursor ion into fragments. The fragment ions are then analyzed in a second MS stage to generate a fragment ion mass spectrum. Fragmentation data is used to determine the precursor ion’s identity based on predicted fragmentation pathways [78]. Additionally, there are several useful “scans” that can be utilized with MS/MS in order to monitor, for example, specific product ions that are known metabolic markers for a particular drug. These tandem strategies are briefly outlined later in this chapter. Tandem MS experiments are performed using either serial stages of MS instrumentation (tandem in space) or an ion trap instrument (tandem in time). When we discuss tandem experiments in IM-MS, we have dealt only with tandem in space arrangements (primarily as a result of the lack of development of ion-trapping-based IM technologies, although it is noted that such a device has been suggested theoretically [79]).

9.4.1 Scanning Modes for Tandem Mass Spectrometry

There are several “scan modes” that are useful in multistage tandem MS for metabolite screening applications. These modes differ only in whether each MS stage is operated in narrow (selected MS) or broadband (full MS) mode. With two MS stages (including a fragmentation stage in between), there are four possible combinations of scan modes that can be utilized. Figure 9.8 illustrates these four scan modes, namely, (a) precursor ion scan (full–selected), (b) neutral loss scan (full–full), (c) product ion scan (selected–full), and (d) selected reaction monitoring (selected–selected). Traditionally, these modes were applied to triple quadrupole instruments, but the general methodology

Figure 9.8 Illustrations of the various MS/MS scanning methods for two tandem MS stages. Fragmentation occurs between the two mass analyzers, as depicted. (a) A precursor ion scan, where the first mass analyzer performs a full scan, while the second mass analyzer is fixed to a given m/z that corresponds to an expected product ion. (b) A neutral loss scan, where both mass analyzers perform a full scan, with the second mass analyzer set to a fixed mass-to-charge difference from the first. Commonly, the analyzer offset corresponds to a known biotransformation. (c) A product ion scan in which the first mass analyzer isolates a particular mass-to-charge value and the second mass analyzer performs a full scan to obtain all resulting fragments. (d) A reaction monitoring scan in which the first mass analyzer selects a specific mass-to-charge value and the second mass analyzer is set to selectively monitor for the appearance of a particular product ion.

has since carried over to other MS/MS instrumentation, such as Q-TOF (quadrupole time of flight), TOF-TOF, and, to some extent, various ion trap platforms. The underlying difference in applying these scan modes to different instrument platforms is in the resulting performance: TOF instruments generally sacrifice sensitivity and broad-range linear response (e.g., quantitative ability) for high speed and high resolution/mass accuracy. Ion traps trade some degree of performance (speed and mass resolution) for experimental versatility; most notably, the capability to do multiple stages of tandem experiments (MS^n , where $n > 2$). Because TOF instruments obtain a broadband mass spectrum, the precursor and selective reaction monitoring experiments are performed post data acquisition. The following is a brief description of each scan mode as the modes are applied in tandem MS/MS experimentation.

The precursor ion scan (Fig. 9.8a) and neutral loss scan (Fig. 9.8b) modes are the first tandem MS experiments that are utilized in a metabolite study. These MS/MS experiments are considered as reasonable preliminary methods since the information gained is broadly encompassing and requires very little *a priori* knowledge regarding the system under investigation. In a precursor ion scan, an expected product ion is selected with the second MS stage, and the first MS stage is scanned through a range of m/z values until the expected product ion signal appears. The product ions of interest represent common metabolic alterations, such as glucuronidation ($M + 176$). Additionally, the second MS stage can be set to monitor the m/z of the parent compound itself in order to discover metabolites that consist an unaltered portion of the

parent compound, such as oxidation ($M + 16$). Because the fragmentation step in an MS/MS experiment results in both fragment ions and fragment neutrals, the mass spectrometer is blind to the latter. To overcome this fundamental limitation, the two MS stages can be set to transmit a fixed m/z difference from one another, representing a characteristic neutral loss. For example, to locate an oxidation product metabolite, the first MS stage is scanned through a range of m/z values and the fragment ion, $M - 16$, is monitored by the second MS stage. This will find all precursor ions that have been oxidized.

The product ion scan (Fig. 9.8c) is the conventional mode for MS/MS experiments. In a product ion scan, a precursor ion m/z is isolated and transmitted by the first MS stage, fragmented, and the entire fragment ion spectrum is obtained in the second MS stage. The product ion scan is useful for characterizing a precursor ion once it has been identified as being of interest. Finally, the reaction monitoring experiment (Fig. 9.8d) is a powerful and specific mode of MS/MS operation used primarily when quantitative information is sought. In this mode, an m/z of interest is selected by the first MS, fragmented, and a specific m/z is monitored by the second MS. Prior knowledge regarding the expected product ions is necessary. A single or multiple set of fragment ion m/z values can be monitored for each precursor ion transmitted by the first MS.

As mentioned previously, these scanning modes were originally developed for triple quadrupole instrumentation, but recent advances in hybrid MS instrumentation has expanded their usage to other platforms. The Q-TOF configuration is a particularly important instrument platform which replaces the final MS stage of a triple quadrupole with a broadband TOF MS. This has the significant advantage that TOF MS performs with greater analyte sensitivity in its conventional broadband MS mode than a quadrupole operating in a full-scan MS mode. The other important analytical advantage that Q-TOF instruments hold over a triple quadrupole platform is higher speed and, consequently, higher sample throughput. Finally, the high mass resolving power capabilities of TOF greatly improve the mass measurement accuracy. Contemporary Q-TOF instruments are capable of resolving powers in excess of 40,000, with a theoretically unlimited mass range. Macromolecules in the MDa (10^6 mass units) range have recently been studied using Q-TOF instruments [80].

9.4.2 High Performance Tandem Ion Mobility–Mass Spectrometry Modes

The addition of IM to multistage MS instruments offers greater experimental flexibility with regard to tandem experiments. For example, the use of an FAIMS device at the front end of an MS instrument introduces an added dimension of chemical noise discrimination that serves to enhance important ion signals appearing at low abundance [81]. A more versatile example is the addition of an IM dispersive stage into a hybrid Q-TOF instrument, which creates the useful MS-IM-MS configuration (specifically, a Q-IM-TOF). Because of the necessary transition between the two vacuum MS stages into the pressurized IM, elevated pressure ion guides are utilized between each stage to efficiently transfer ions into and out of the IM device, which creates an advantageous addition of two collision cells in the MS-IM-MS instrument configuration. Thus, collisional activation of ions can be accomplished before or after the IM separation, which creates a number of useful tandem arrangements. The next section deals with the various tandem configurations afforded by the MS-IM-MS configuration,

and we consider some of the added information that can be gleaned from each stage of tandem analysis. Regarding nomenclature, the hyphen designates two coupled analyzers (e.g., IM-MS) while the forward slash designation (e.g., MS/MS) denotes tandem capabilities (i.e., a collision cell between the two components).

When considering an analytical configuration that brackets a mobility separation between two mass analyzers (MS-IM-MS), the first possibility is to select an m/z window with the first MS stage and immediately induce fragmentation before the IM-MS analysis (i.e., MS/IM-MS). This will generate a comprehensive 2D IM-MS spectrum of resulting fragment ions (Fig. 9.9a). This strategy is identical to performing a product ion scan, but with the added dimensionality of the IM separation, resulting in separation of product peaks based on both mobility and mass-to-charge ratio. The practical benefit is the separation of product ions in chemical space, allowing for the distillation of the fragmentation spectrum. However, isobaric species will not be separated before fragmentation, and the resulting product ion spectrum may reflect multiple isobaric species not easily differentiated.

An alternative mode of operation is to first select an m/z of interest, mobility-separate, and then fragment the ions following the IM region (i.e., MS-IM/MS). As a result, a particular mass of interest is dispersed based on mobility before fragmentation and secondary mass analysis. An example spectrum is contained in Fig. 9.9b. Because ion fragmentation follows the IM separation, the resulting fragment ions will have mobility drift times correlated to their precursor ion signal. Thus, this method allows for the initial separation of isobaric ions based on their different mobilities, while simultaneously correlating the product ions to their precursors. Thus, both chemical noise and isobaric signal overlap are attenuated through this fragmentation method. The MS-IM/MS method can greatly simplify analyte identification based on the removal of contaminating product peaks contributed by isobaric ions.

A third mode of operation that can be utilized in the MS-IM-MS configuration is to isolate an m/z in the first MS stage, induce dissociation, mobility-separate the resulting fragments, and finally, fragment once again before the secondary mass analysis (e.g., MS/IM/MS). This mode of operation (Fig. 9.9c) results in mobility-correlated secondary product ions. Figure 9.10 contains tandem data for the IM-MS analysis of the small carbohydrate, lacto-*N*-fucopentaose 1 and illustrates two modes of tandem IM-MS. In Fig. 9.10a, the ion fragmentation occurs before the IM-MS analysis, which results in a two-dimensional spectrum of fragment ions separated in both mobility and mass space. In Fig. 9.10b, ions are induced to fragment both before and immediately following the IM analysis, resulting in a second stage of fragmentation (a pseudo-MS³ experiment). In the latter example, the secondary fragments align themselves to the precursor ion signals in which they originated since the IM separation occurs before their formation. The novel aspect of this mode of tandem experimentation (MS/IM/MS) is that simultaneous ion activation can be achieved, generating a complete precursor and fragment ion spectrum during each experimental measurement cycle.

9.4.3 Advantages of High Mass Accuracy and High Resolution in Metabolite Identification

In drug metabolism studies, the molecular formula of a metabolite of interest is a key piece of information. This information is most easily obtained by measuring the exact mass of the ion to high accuracy. High resolution MS can obtain a mass measurement

Figure 9.9 Three different tandem modes for MS-IM-MS instrumentation. Each two-dimensional spectrum corresponds to a single m/z value isolated by the first MS stage. (a) MS/IM-MS mode in which fragmentation precedes the IM-MS analysis. (b) MS-IM/MS mode in which the mobility spectrum is generated before ion fragmentation, resulting in alignment of the fragment ions to their precursor ion's measured mobility value. As illustrated, this tandem mode is particularly useful for isobaric ions that cannot be differentiated by MS alone. (c) MS/IM/MS mode in which an isolated m/z value is fragmented both before and after the ion-mobility analysis, resulting in parallel fragment ion alignment, correlating to their respective precursor ion signals. In these examples, only singly charged ions are considered.

Figure 9.10 Ion mobility–mass spectra of the small carbohydrate, lacto-*N*-fucopentaose 1, illustrating two tandem IM-MS modes. (a) Spectra from fragmentation before IM-MS analysis, which results in dispersion of fragment ion signal across both dimensions of data analysis. (b) Spectra resulting from two stages of fragmentation, one before the IM analysis and one immediately following the IM. In the latter case, fragment ion signal is dispersed across the mobility dimension and secondary fragment ion signals align isobaric in mobility, resulting in simultaneous fragmentation of all ions resulting from the first stage of activation. *Source:* For the mass spectra (in both (a) and (b)), the carbohydrate nomenclature used is from Domon and Costello [82]. Adapted from McLean JA, Fenn LS, Enders JR, Mass Spectrometry Imaging, Methods in Molecular Biology 656, Rubakhin, SS, Sweedler, JV (eds.) 2010. Fig. 21.7, with kind permission from Springer Science+Business Media.

with high precision, which factors directly into the accuracy of the mass measurement. By obtaining an accurate mass measurement with high confidence, one can narrow down the number of possible molecular formulas pertaining to the measured mass.

When utilizing high resolution MS, an approach has been applied to metabolite identification that relies primarily on high mass accuracy to query the entire sample post separation [83]. This method is termed MS^E and functions by initially acquiring data over a large mass range (ca. 100–1000 Da). Subsequently, collision energy is imparted to the same range of ions in a ramped method from low to high energy. This results in data that combines the full scan with corresponding fragments. Using the high mass accuracy and drift time separations of the instrument, product ions can be correlated back to their respective precursor ions based on mass defect and mobility. This resolves the issue of discarding ions on the basis of selective fragmentation, as this method allows for the fragmentation of all ions within a given time range. High mass accuracy is maintained through the use of an internal standard for proper calibration. What results is the ability to perform broadband fragmentation and monitor product ion transitions, as commonly done in scanning experiments, over an entire mass range. A fundamental limitation lies in the fragmentation of isobaric species that are inherently present in complex samples, as product ions for both isobars will be present in the fragmentation spectrum, resulting in convoluted data sets. This is commonly addressed

by performing a preionization separation. Fortunately, the IM separation can distinguish isobars in the mobility dimension. As a result, an additional degree of discrimination is present in compiling a list of product ions for a given precursor.

Tandem MS inherently has limitations. Most notably, this method is insensitive to low intensity precursor ions, as these are often overlooked by automated systems if a particular peak is transient in nature. Selected precursor ions must be well above the limits of detection for a given tandem platform in order to generate meaningful tandem spectra. Isobaric species, which would commonly convolute tandem spectra, may be separated using IM post ionization separations to resolve isobars. While IM-MS enhances tandem experiments, currently, IM separations are insufficient for the routine resolution of structurally similar isobars, for example, compounds that differ by a single chiral center. This is where high resolution structural measurements, such as NMR, are required. However, these methods allow for the relatively rapid interrogation of complex samples, allowing distillation of robust data sets to significant analytes.

We began this chapter by stating the technological challenges of metabolite analysis are substantial. While this is accurate, the number of metabolites expressed by eukaryotes is small in comparison to the number of proteins, which is estimated somewhere at ca. 200,000 for humans. If IM-MS and related technologies are to be commissioned into the global “omics” initiatives, then there is perhaps no greater potential for impact than in metabolite analysis. Future work should seek to implement the real-time acquisition of metabolic information to better represent the dynamic nature of the metabolome. The temporal resolution necessary to understand transient biological responses will likely require the ability to acquire spectra at a rate that exceeds our current analytical capacity using preionization separations. This conundrum lends itself strongly to the case for IM-MS as a means of rapid analysis of drug metabolism. By coupling IM-MS with microfluidics that allow for the trapping and maintenance of cell colonies, a global profile of a microenvironment can be acquired with high temporal resolution. This permits a more complete understanding of the underlying metabolic processes that preclude particular metabolites, while potentially circumventing the dilution issue commonly associated with bulk cultures. Although many technical issues exist with coupling microfluidic environments directly to IM-MSs (e.g., ion suppression by non-informative, high abundance metabolites, and salts), these are surmountable and have been addressed in a modular fashion.

9.5 SUMMARY

IM spectrometry is the separation of gas-phase ions on the basis of differential velocities through an inert buffer gas under the influence of an electric field, this rate being termed *mobility*. Four main IM separation methods exist (drift tube IM spectrometry, traveling wave IM spectrometry, high field asymmetric waveform IM or DMS, and differential mobility analyzer), each utilizing a different approach for separations of gas-phase ions. These methods, although present in various geometries and grounded in disparate physical principles, have the common thread of performing a postionization separation based on mobility. Drift tube and traveling wave IM temporally separate ions along the same space, which has the advantage of generating a broadband spectrum for each measurement cycle, while limited to separating discontinuous

ion pulses. High field asymmetric waveform IM and differential mobility analyzers separate ions along different spatial trajectories, allowing for a continuous beam of ions to be transmitted, which possess a narrow band of mobilities. The latter techniques must be scanned across an instrument parameter (a voltage) to generate a broadband IM spectrum.

Each IM separation method has been integrated with MS for two-dimensional separations based on both mobility and mass-to-charge ratio. These two analytical methods are readily coupled (IM-MS), as both separations occur post ionization, and result in rapid separations occurring on the order of milliseconds and microseconds, respectively. This temporal disparity allows for hundreds of mass spectra to be obtained for each mobility spectrum. For high performance MS applications, broadband dispersion mobility separations are commonly implemented, which allow for global metabolome profiles to be obtained. Because the ionic mobility is a function of gas-phase size and a function of mass, a two-dimensional IM-MS analysis results in a clustering of data along a narrow region of mobility and mass separation space. Thus, the degree of orthogonality between IM and MS is low; however, the rate at which information is generated is very high, with signal peak production rates ca. two orders of magnitude greater than other analytical separations. The correlation between mobility and mass data exhibits a dependence on intramolecular forces, monomer subunit composition, and degree of branching, which allows for the preliminary determination of biomolecular and metabolite class based on mobility. IM-MS allows spectra acquisition temporal resolution on the order of milliseconds, dispersion of chemical noise in two dimensions, separation of isobaric species based on structural differences, and preliminary determination of molecular class based on mobility. IM-MS is also readily coupled to any liquid-phase preionization separation through ESI.

The ability to perform fragmentation between separations in an IM-MS instrument allows for identification studies (tandem experiments) that enhance precursor ion identification confidence. Fragmentation is commonly prefaced with a mass selection step using a scanning mass analyzer (e.g., a quadrupole MS) in order to isolate a single mass-to-charge window. Fragmentation can occur either before (MS/IM-MS) or after (MS-IM/MS) the IM separation, resulting in product ions or isobaric precursor ions separated in mobility space, respectively. Fragmentation before mobility separation results in mobility-resolved product ions, and these product ions can be further fragmented after mobility separation (MS/IM/MS), resulting in secondary product ions that can be correlated to primary product ions on the basis of the congruent mobilities. Broadband fragmentation can also be performed on relatively simple samples using a large mass window (ca. 100–1000 Da), a ramped fragmentation energy profile, and a high performance mass spectrometer. In the latter example, product ions are correlated to precursor ions based on mass defect. Increased confidence is obtained through the use of mobility correlation to this broadband fragmentation method, as isobaric ions will convolute data otherwise.

10.1 INTRODUCTION

The inductively coupled plasma mass spectrometry (ICP-MS) technique was developed in the 1970s based on the need for a mass spectrometer capable of accepting solid mineral samples and providing multielement analyses at levels down to 10 ng/g in an analysis time of few minutes [1]. Thus, the technique was the successor of atomic absorption spectrometry and intensively used for analysis of geological samples.

In the last decades, the technique has evolved as hyphenation to different separation systems and has become the state of the art in the research field often referred to as *metallomics*. This research field has been described as “the comprehensive analysis of the entirety of metal and metalloid species within a cell or a tissue type” [2]. This field includes speciation analysis of essential and toxic elements as well as interaction of metal-based drugs (MBDs) with cell constituents and macromolecules.

The major advantages of the ICP-MS technique are the capability of multielement analysis, a very large sensitivity, and on-line sample introduction. The most

important feature, however, is that the detector response of the ICP-MS, in contrary to UV- and ES-MS (electrospray-mass spectrometry) detection, is independent of the analyte structure. Thus, unknown metabolites can be detected and quantified based on the ICP-MS detectable element in the metabolites. This makes ICP-MS an obvious detector in analysis of MBDs.

10.2 ICP-MS

10.2.1 The Instrument

ICP-MS is a hard ionization mass spectrometric technique that produces positive ions of single atoms in a high temperature argon plasma. Most often, the sample is introduced in solution, although solid material can be introduced using laser ablation. For analysis of pharmaceuticals, however, liquid sample introduction is predominant. The sample is pumped into a nebulizer, where an aerosol is produced by a flow of argon and transferred to a spray chamber. In the spray chamber, large droplets are discarded allowing only a fine mist of liquid to enter the argon plasma where the aerosol is desolvated, molecules are vaporized and decomposed into atoms, and finally the atoms are excited and ionized.

The argon plasma is an electric conducting gaseous mixture of argon, argon ions, and electrons sustained by a fluctuating magnetic field produced by a radio frequency induction coil. The plasma temperature of 6–10,000 K gives rise to complete sample combustion and a very efficient ionization. Positively charged ions are extracted from atmospheric pressure into the vacuum of the mass spectrometer through a set of cones. In the mass spectrometer, the ions are separated based on their mass to charge ratio (m/z). In routine instruments, the mass spectrometer is most often quadrupole based, operating at mass ranges of 3–300 with unit resolution, although high resolution instruments with a resolution of up to 10,000 are also commercially available [3].

The ionization efficiency of the plasma is dependent on the first ionization energies of the measured elements (Table 10.1). Metals are, in general, efficiently ionized and ICP-MS is therefore intensively used in inorganic analysis as the detection limits for most elements are at the subparts per billion level.

10.2.2 Interferences

One major challenge in ICP-MS analysis is the presence or formation of interferences. These are often divided into spectroscopic and nonspectroscopic interferences. Spectroscopic interferences appear at the same m/z value as that of the analyte, for example, the overlap of ^{196}Hg on ^{196}Pt . Such an overlap can most often be overcome by the choice of another isotope of the analyte. Another group of spectroscopic interferences is the polyatomic ions derived from the plasma gas (e.g., $^{40}\text{Ar}_2^+$), atmospheric gasses, sample solvent, or sample matrix constituents (e.g., $^{12}\text{C}^{40}\text{Ar}^+$ on $^{52}\text{Cr}^+$). The number of possible interferences decreases with increasing atomic mass, hence few interferences compromise the measurement of metals such as platinum and gold compared to the lighter metals such as iron and chromium. A comprehensive list of possible interferences on most elements has been given by May and Wiedmeyer [4]. To avoid polyatomic interferences, instruments equipped with a collision or reaction cell can

TABLE 10.1 First Ionization Energy and Degree of Ionization for Selected Elements

Atomic Number	Element	Most Abundant Isotope	Percentage	First Ionization Energy (kJ mol)	Degree of Ionization (%)
12	Carbon	¹² C	98.9	1086	5
15	Phosphorus	³¹ P	100	1012	33
16	Sulfur	³² S	95.0	1000	14
18	Argon	⁴⁰ Ar	99.6	1520	0.04
22	Titanium	⁴⁸ Ti	73.8	658	99
23	Vanadium	⁵¹ V	99.8	650	99
26	Iron	⁵⁶ Fe	91.7	759	96
33	Arsenic	⁷⁵ As	100	947	52
44	Ruthenium	¹⁰² Ru	31.6	711	96
51	Antimony	¹²¹ Sb	57.4	834	78
64	Gadolinium	¹⁵⁸ Gd	24.9	593	93
74	Tungsten	¹⁸⁴ W	30.7	770	94
78	Platinum	¹⁹⁵ Pt	33.8	870	62
79	Gold	¹⁹⁷ Au	100	890	51
83	Bismuth	²⁰⁹ Bi	100	703	92

be used. In a collision cell, the polyatomic ions are disintegrated by collision with an inert gas such as He, while in the reaction cell, the interference is removed from the m/z value of the analyte by reaction with a gas resulting in reaction products with m/z values different from the analyte [5]. These second-generation instruments are most commonly used today. Use of high mass resolution sector field instruments is an alternative, but a much more expensive solution to the interference problems. These instruments are capable of resolving minute differences in the masses of the analyte ion and the interfering ions [6].

The nonspectroscopic interferences are observed as changed sensitivity of the analyte signal induced by matrix constituents, for example, high salt concentrations. These interferences may be caused by changes in nebulization and ionization efficiency, in ion transport efficiency, in ion extraction, or combinations of these [7]. Elements with low mass or high ionization energies are most severely affected [8]. The nonspectroscopic interferences are often referred to as *matrix interferences*.

10.3 QUANTITATIVE DETERMINATIONS

The multielement capabilities of ICP-MS are routinely applied in the related area of determination of inorganic impurities in drugs and active pharmaceutical ingredients, an area not covered in this chapter, but that has been reviewed recently [9]. Drugs containing metals are often analysed by ICP-MS due to the low limits of detections, high sensitivity and few interferences for most drug related metal-ions (Pt, Ru and Au), few interferences are present. The multielemental capabilities of ICP-MS are rarely used, although an internal standard or a few other elements are sometimes measured along with the selected metal in order to correct for changes in instrument sensitivity over time or to monitor potential polyatomic interferences. The determination of total metal-containing drugs using ICP-MS is often applied in metabolism, distribution, and

excretion studies or in uptake experiments using cancer cell line models. This requires analysis of biological samples such as serum, urine, or cell samples. These are all difficult to analyze due to the small sample volume available or matrix effects from salts, proteins, and other biomolecules. Thus, sample preparation and quantification are critical in order to achieve accurate and precise results.

Two different approaches can be chosen for the sample preparation of biological samples. Most simple is the application of a dilution with an appropriate diluent [10–12], thereby keeping the drug in solution in its existing form. For dilutions, there is a risk of coprecipitation of the metal, as proteins and other such molecules might precipitate over time. Alternatively, acid digestion with concentrated acids (plus hydrogen peroxide) can be applied, reducing organic molecules to CO₂ and H₂O and bringing the metal ions in their ionic form [13–18]. In general, acid digestions should be preferred, resulting in more stable solutions of the metal ion of interest. Another advantage of acid digestions is that quantification using external calibration is possible, while the more laborious standard addition calibration or careful preparation of matrix-matched standard is needed, when samples are simply diluted before analysis. Acid digestions are, however, more time consuming and require more sample handling steps. Most accurate and precise quantification is achieved applying isotope dilution using an enriched isotope of the analyte as a standard (e.g., ¹⁹⁴Pt for the quantification of platinum). Isotope dilution quantification can be either unspecific applying a solution of the enriched isotope as standard or specific for which the enriched isotope is incorporated into a specific compound, for example, [¹⁹⁴Pt(NH₃)₂Cl₂]. These approaches were used by Sar *et al.* [19] for the accurate and precise determination of platinum in DNA samples.

Many of the drugs are lipophilic, and adsorption to the surfaces of sample preparation vials and sample wells can be a problem. This problem was addressed by Egger *et al.* [17], who developed a protocol for determination of the cellular uptake of metal compounds in adherent cancer cell lines, a protocol that takes into account adsorption and blank correction. Utilizing this protocol for determination of the cellular uptake of Pt and Ru drugs, they were able to measure the cellular uptake experiments with good precision and accuracy.

Certified reference materials (CRMs) are widely used for validation of ICP-MS methods for determination of total metal concentrations, but for Pt and Ru, only a few biological CRMs with certified concentrations exist, and there is a clear need for new CRMs in the metallo-drug area. Thus, accuracy and precision are most often evaluated using in-house quality control samples. Bettinelli [11] carefully evaluated the analytical uncertainty associated with the determination of total Pt in plasma, plasma ultrafiltrate, and urine using ICP-MS. The instrumental LOD was at submicrogram per liter level and the limits of quantification (LOQs) (10σ) were at low microgram per liter level for plasma, ultrafiltrate, and urine [11,12]. Similar detection limits led to an LOQ of 0.5 μg/kg in DNA samples [12]. Figures of merit in the same range have been found by others [13,15,16,18], while even better LODs can be achieved with high resolution ICP-MS instrumentation [14].

10.4 LC-ICP-MS

Coupling of LC (liquid chromatography) systems with flow rates of 0.1–1 mL/min to ICP-MS is quite simple, as these flow rates are readily compatible with the sample

Figure 10.1 Schematic overview of LC-ICP-MS. *Source:* ©Agilent Technologies, Inc. 2010. Courtesy of Agilent Technologies, Inc., with permission.

uptake around 1 mL/min for the ICP-MS instrument. The coupling of an LC system to an ICP-MS instrument is illustrated in Fig. 10.1. Several reviews on this coupling have been published [20–22]. Most of the early work on LC-ICP-MS coupling was performed using ion-exchange chromatography, as the eluents in such systems are, most often, aqueous buffers and elution is regulated by the salt concentration. As the ICP-MS, in contrast to organic MS, is quite tolerant toward moderately high salt concentrations, ion-exchange columns were, for a long period, the most popular columns for the hyphenation.

10.4.1 Organic Solvents

When more lipophilic substances, such as pharmaceuticals and their metabolites, have to be separated, reversed phase (RP) chromatography involving eluents containing large amounts of organic solvents is the most common separation principle used. In most drug metabolism studies, linear gradient elution from 5% to 95% organic solvents is often applied as a standard procedure. This introduces several analytical challenges, as the plasma only tolerates small amounts of organic solvents. Severe suppression of the signal followed by plasma instability is observed by increasing the organic solvent load and eventually the plasma is extinguished. The influence of organic solvents on the plasma is complex and involves interaction between solvent and plasma as well as change of aerosol characteristics in the spray chamber [23,24]. Introduction of organic solvent cools the plasma and changes ionization characteristics, leading to decreased sensitivity. In contrast, the addition of organic solvent to an eluent decreases surface tension and improves the aerosol by changing the droplet distribution toward smaller droplets, which results in improved transport efficiency and increased sensitivity. However, the interaction between plasma and solvent most often dominates, and increasing the radio frequency (RF) power with increasing organic solvents is necessary.

As the sensitivity of the ICP-MS signal is highly dependent on the organic solvent content of the solution, and the sensitivity in general decreases when the amount of organic solvent is increased, gradient elution would compromise quantifications, as sensitivity would change with the elution gradient.

Several approaches for minimizing the influence of organic solvent on the sensitivity have been reported. Solvent combustion could be enhanced by adding oxygen to the nebulizer gas. A combination of 5% oxygen in the nebulizer gas and spray chamber cooling has been a common setup reported in many studies. The plasma load can be reduced by reducing the eluent flow rate or by flow splitting, cooling the spray chamber, or complete removal of the solvent before introducing to the ICP-MS. Complete removal of the solvent is used in membrane desolvation units, where the eluent is heated and removed. These systems are often used in combination with an ultrasonic nebulizer (Fig. 10.2). In principle, these systems should allow for using gradient elution. However, great care should be taken that the analyte itself does not escape with the solvent, and several studies have shown that different species show different sensitivities in such systems. A review of different approaches to circumvent the problems

introduced by organic solvents in drug metabolism studies of metal-containing and nonmetal drugs has recently been published [25].

10.4.2 Small Bore Columns and Low Flow Nebulizers

The common chromatographic column inner diameter was 4.6 mm just a decade ago, increasing interest in “green chemistry,” and subsequent interest in diminishing the organic solvent consumption has led to decreasing column diameters to 2 mm, 1 mm, and even down to capillary sizes of <100 μm . The increasing interest in analyzing very small sample sizes has fortified this tendency. Thus, the use of microbore columns in combination with low flow nebulizers has become increasingly popular for hyphenation with ICP-MS.

The lower flow of microbore columns demands the use of low flow nebulizers capable of delivering stable nebulization of flow rates in the order of 1–100 $\mu\text{L}/\text{min}$. These are known as the *direct injection high efficiency nebulizers* (DIHENs). Although the sample flow is lowered with these nebulizers, the sensitivity is still good, as the nebulizers introduce the whole sample flow into the plasma in contrast to the use of spray chambers where only a few percent of the sample reaches the plasma. The first of these nebulizers was very fragile and difficult to operate, while newer systems have become more robust. An example of a microflow sample introduction system is shown in Fig. 10.3. The handling of such systems, however, is still not a matter of routine [26].

Although the use of narrow-bore columns and low flow rates diminish the problem with plasma instability, stable signals are only obtained with isocratic elution schemes. A new approach to circumvent the influence of changing sensitivity is to oppose the gradient by introducing a counterflow, resulting in a constant load of organic solvent to the plasma[27].

Examples of LC-ICP-MS applications are listed under the individual elements in the following sections. The structures of the most commonly analyzed MBDs are given in Fig. 10.4.

10.5 CE-ICP-MS

Capillary electrophoresis (CE) is based on the migration of ions in an electric field. Thus, this separation principle is different from LC and could be a useful alternative technique. The main idea behind coupling of CE to ICP-MS is to exploit the sensitive and element-specific detection of ICP-MS with the high resolution of CE. Many MBDs have no or limited UV absorption limiting the use of CE-UV. Although hyphenation of CE and ICP-MS is not simple, it offers several advantages: a very low injection

Figure 10.4 Structures of selected metal-based drugs.

volume in nanoliters, an alternative separation method to LC, low buffer consumption, and high number of theoretical plates.

10.5.1 Interfaces

The first paper on hyphenation of CE and ICP-MS was published by Olesik in 1995 [28], and since then, several papers have presented different ways of hyphenation. Today, two CE-ICP-MS interfaces are commercially available. In contrast to LC-ICP-MS, hyphenation is not straightforward as the low flow from the CE must be adapted to the flow acquired by the nebulizer, the electric connection must be maintained at the outlet of the CE capillary, and any laminar flow in the CE capillary must be avoided due to suction from the nebulizer. Figure 10.5 shows the hyphenation of CE and ICP-MS through a sheath flow interface. Here, a sheath flow is used to obtain a total flow of 5–10 $\mu\text{L}/\text{min}$, the electric connection is maintained through a grounded Pt electrode placed in a sheath liquid, a low consuming nebulizer is used, and liquid levels in the CE and sheath liquid are adjusted to avoid siphoning. A detailed description and technical aspects of hyphenation of CE and ICP-MS can be found in a recent review [29].

Figure 10.5 Schematic overview of CE-ICP-MS with the CEI-100 interface. *Source:* With permission from CETAC Technologies.

10.5.2 Quantitative Aspects

CE-ICP-MS has primarily been used for qualitative and semiquantitative analyses. A major drawback of the technique is changes in sensitivity during the day. Two ways of circumventing this problem has been proposed: addition of a trace element (external standard) to the sheath liquid [30] and the use of internal standard in the samples [31]. This leads to improved precision. Figure 10.6 shows an electropherogram of

Figure 10.6 CE-ICP-MS analysis of incubation of plasma and carboplatin for 48 h at 37°C. Sodium diatrizoate is added as an internal standard before analysis, and In is used as an external standard. (See color insert.)

carboplatin incubated in plasma. Indium was added to the sheath liquid, and sodium diatrizoate (iodine) was used as an internal standard to correct for changes in sensitivity.

ICP-MS is a mass sensitive detector, meaning the signal is dependent on the total amount of analyte in the plasma. This explains why the detection limit for CE-ICP-MS is higher than that for LC-ICP-MS, as the injection volume is in nanoliters and

microliters, respectively. Furthermore, the sample is diluted due to the use of a sheath flow [32].

CE-ICP-MS has been applied to the analysis of various MBDs, with primary focus on stability and interactions with biomolecules, particularly proteins. Most work is based on model systems using human serum albumin (HSA), transferrin (Tf), or plasma/serum. However, the method has been applied to the analysis of a plasma sample from a patient treated with the experiment Ru drug KP1019 [33]. Table 10.2 gives an overview of some of the recent research on MBDs using CE-ICP-MS.

The main challenge of analyzing proteins is to minimize adsorption due to hydrophobic or ionic interactions between the protein and the capillary surface, which leads to broad or tailing peaks. Using coated CE capillaries or adding a modifier to the buffer minimizes the problem. Furthermore, the background electrolyte should resemble the incubation buffer and physiological conditions should be used during sample preparation to avoid alternation of weak interactions during sample preparation and analysis [34]. A high background electrolyte concentration also increases the likelihood of clogging the nebulizer [32].

CE-ICP-MS analysis is still not a matter of routine. The technique has been compared to capillary LC-ICP-MS for analysis of metalloproteins. Using the same injection volume, similar performance of the two systems was observed. Capillary LC-ICP-MS was more robust and offered the opportunity to inject a larger sample volume and use on-line preconcentration of the sample before analysis. This is important when analyzing real samples with low concentration [40]. Thus, over time, CE-ICP-MS systems may be outperformed by capillary LC-ICP-MS in most applications.

10.6 LA-ICP-MS

In contrast to LC-ICP-MS, for which samples must be dissolved before analysis, laser ablation (LA)-ICP-MS offers the opportunity to measure solid samples by laser ablation of a small sample quantity, which is transferred to the ICP-MS. LA-ICP-MS has not gained great prevalence for the analysis of drugs. A general problem with LA-ICP-MS quantification is that it is difficult to obtain suited standards. The first application of LA-ICP-MS in the analysis of MBDs was to identify the platinum-containing proteins in *Escherichia coli* cells treated with cisplatin before separation with gel electrophoresis [41]. Examples of recent applications are quantification of Pt along a single hair strand from a patient treated with cisplatin [42] and scanning of kidney tissue from a mouse treated with cisplatin to create images of the distribution of ^{63}Cu , ^{64}Zn , and ^{196}Pt [43].

10.7 APPLICATIONS

The first application of LC-ICP-MS for MBD analysis is analysis of the gold-containing drug, auranofin [44]. The hydrolysis products of cisplatin and reaction products with methionine, cysteine, and glutathione were investigated using ion-pair LC-ICP-MS [45]. In addition to monitoring interactions with small biomolecules and metabolites, the interaction with proteins has been of general interest. In early investigations, the fraction of free and protein-bound metal was analyzed after ultrafiltration, after

which on-line-SEC-ICP-MS monitoring the interaction between proteins and Pt- or Ru-based drugs was introduced [46]. Following is an overview based on the individual elements.

10.7.1 Platinum

Since Rosenberg, in 1965 by accident, discovered cisplatin [47], various platinum compounds have been synthesized and tested for their cytotoxicity. Today, three Pt-based drugs are approved worldwide as anticancer drugs. The structures of cisplatin, carboplatin, and oxaliplatin are given in Fig. 10.4. Cisplatin is very efficient in the treatment of certain cancer types, particularly testicular cancer and some solid tumors. The limited application; severe side effects such as kidney damage, loss of hearing, damage to the nervous tissue; and intrinsic or acquired resistance to the treatment have led to the synthesis of many new Pt-based drug candidates. At first, most new drug candidates were cisplatin analogs, based on a square planar Pt(II) center with two monodentate or one bidentate leaving groups, but the oral Pt(IV) drug satraplatin (JM216) has also entered clinical trials [48]. In total, around 40 Pt-based drugs have been investigated in clinical trials and more than 1000 have been synthesized [49].

10.7.1.1 ICP-MS and Platinum. Platinum has six stable isotopes ^{190}Pt , ^{192}Pt , ^{194}Pt , ^{195}Pt , ^{196}Pt , and ^{198}Pt . The three most abundant isotopes ^{194}Pt , ^{195}Pt , and ^{196}Pt have a relative abundance of 32.9%, 33.8%, and 25.2%, respectively. They are all subject to isobaric interference of ^{178}HfO , ^{179}HfO , and $^{180}\text{HfO}/^{180}\text{WO}$, respectively, but this is normally not a problem, as Hf and W are not present in biological samples and the formation of metal oxides can be controlled through plasma conditions. Furthermore, ^{196}Pt is subject to isobaric interference of ^{196}Hg . Instrumental detection limits for determination of total Pt in subnanogram per liter range have been reported for quadrupole-based ICP-MS [18], while detection limits for LC-ICP-MS have been reported to be around or below 1 $\mu\text{g/L}$ using a quadrupole and the detection limit improved by a factor of 10 using sector field ICP-MS [50,51].

10.7.1.2 DNA-Binding Mechanism. The general mechanism of Pt-based drugs involves binding to DNA in the cell nucleus. When cisplatin enters the cell, it undergoes hydrolysis because of low chloride concentration inside the cell, $\sim 5\text{ mM}$. The major binding site for cisplatin on DNA is on the guanine base, and it forms an intrastrand cross-link [52]. DNA is bent leading to inhibition of transcription and in the end to apoptosis or necrosis [53]. As formation of DNA adducts is believed to be crucial for cell death, studies of the nature of the binding have been conducted. Recently, an LC-ICP-MS method was developed to quantify cisplatin–DNA adducts formed after incubation of cisplatin cell carcinoma cultures. Three methods all applying isotope dilution analysis (IDA) and species-specific or unspecific spiking were used for quantification. A method for quantifying the amount of Pt bound to DNA, extracted from peripheral blood mononuclear cells and tumor tissue from patients treated with cisplatin, has been developed. The results were compared to the alternative ^{32}P -postlabelling method and found to be more precise, sensitive, and less laborious [54].

10.7.1.3 Interaction Studies. Pt(II) is a soft metal with a high affinity toward soft ligands such as sulfur. Therefore, interactions between biomolecules and Pt-based drugs are common. Table 10.3 gives an overview of some of the recent research obtained using LC-ICP-MS. Cisplatin, carboplatin, and oxaliplatin are all administered intravenously. Therefore, interactions with serum protein have gained particular interest.

One of the features of ICP-MS is multielement detection. This has been utilized in several papers on interaction with proteins and biomolecules. All serum proteins contain sulfur as a result of the presence of the sulfur-containing amino acids, methionine and cysteine. This gives the opportunity to simultaneously monitor Pt and S in interaction studies. In addition, Tf contains iron, and in serum, around 30% of the Tf is loaded with iron. This has been used to demonstrate that the incubation of transferrin with cisplatin did not displace iron from transferrin [19,65]. Recent studies, however, contradicted this observation [65]. Interaction between metallothionein (MT) and cisplatin has also been monitored with Zn, Cd, and Pt [56,66]. Sensitivity of S is much lower than that of Pt. This is due to the high ionization potential of S and the fact that the most abundant isotope ^{32}S (95%) is subject to interference from $^{16}\text{O}_2$. Instead, ^{34}S (4.2%) can be monitored or a dynamic reaction cell can be used to move $^{32}\text{S}^+$ to $^{32}\text{S}^{16}\text{O}^+$. Figure 10.7 shows the simultaneous monitoring of Pt, S, and Fe in iron-saturated apotransferrin incubated with cisplatin [19].

10.7.1.4 Stability of Pt-Based Drugs During Sample Preparation and Analysis.

Whenever performing speciation analysis, the integrity of the sample is of primary concern. However, only few papers have dealt with this problem. Tran *et al.* [67] analyzed cell lysates from T289 malignant melanoma cells exposed to cisplatin using hydrophilic interaction chromatography (HILIC)-ICP-MS. Chemical lysis, osmosis, and freeze thaw were compared. Chromatograms of the lysates showed different results, stressing the need for critical evaluation of the lysis method. In addition, they also found a difference in the total amount of Pt extracted from the cells using the aforementioned lysis methods. Esteban-Fernandez *et al.* [60] evaluated the interaction strength between cisplatin biomolecules under denaturing conditions using LC-ICP-MS and found that the interaction was strong, as no changes were observed. As previously mentioned, conditions applied during separation may affect the binding of metals to proteins [34]. The choice of mobile phase may also lead to artifacts. Heudi *et al.* [68] found that phosphoric acid, in contrast to formic acid, interacted with monoaquacisplatin. The above-mentioned papers all demonstrated the need to carefully evaluate the sample preparation method and separation method in order to avoid altering the sample and creating artifacts.

10.7.1.5 Uptake in Cancer Cells—Total Determination of Pt in Various Fractions.

In the search for new Pt drugs, there has been an interest in establishing a relationship between the cytotoxicity and the uptake of Pt in the cells and the amount of Pt bound to DNA. Also, the distribution of Pt between different cellular compartments has been investigated. After incubation of the drug, the cells were divided into nucleus, DNA, mitochondria, cytosol, and medium. The concentration was determined relative to the amount of protein, which was used as a measure of the amount of cells. In addition to the determination of distribution in the cellular compartments, ICP-MS has been used to determine the pharmacokinetic parameters. A recent review summarizes different investigations on the pharmacokinetic parameters for oxaliplatin [69]. An overview of selected papers on total determination of Pt can be found in Table 10.4.

10.7.1.6 Drug-Delivery Systems. Owing to the side effects from treatment with Pt drugs, drug-delivery systems have gained attention. A targeted delivery of the drug to the tumor could enhance efficacy and minimize side effects. ICP-MS has been used to monitor the amount of encapsulated drug and the uptake of drug in cancer cells. Passive targeting takes advantage of the enhanced permeability and retention (EPR)

of macromolecules, nanoparticles, and liposomes. EPR arises because of both vascular permeability stimulated by extravasation and increased retention from the inefficient drainage of macromolecules by the lymphatic system [73]. Several ways have been explored: encapsulation of the drug in nanoparticles [74,75] or microspheres [76] and binding of the drug to macromolecules [77,78].

10.7.2 Gold

Gold-containing drugs were originally developed for the treatment of arthritis [79]. In recent years, gold complexes have also attracted attention as possible anticancer drugs. Numerous gold(I) complexes have been evaluated for cytotoxicity and antitumor activity [80]. Also, gold(III) complexes demonstrate antitumor properties, an example is Auoxo6, a binuclear gold(III) complex (Fig. 10.4) [80,81]. Gold(III) complexes typically display the same electronic configuration and similar structure and reactivity as platinum(II) complexes. However, apoptosis induced by gold(III) complexes seems to be triggered by mitochondrial damage and not by prevention of DNA replication, as in the case of cisplatin [80]. Despite the efforts in discovering and developing new gold complexes for cancer treatment, no drugs have yet been approved. Hence, gold-containing drugs are still limited to arthritis treatment. These comprise the polymers of sodium thiopropanolsulfonate-*S*-gold(I), sodium bis(thiosulfate), sodium aurothiomalate (myocrisin), and aurothioglucose (solganol) and the monomer triethylphosphine-goldtetraacetylthioglucose (auranofin and Ridaura). Recently, a new promising field applying gold nanoparticles as drug-delivery vehicles has emerged. Gold nanoparticles can be functionalized with a thiolated poly(ethyleneglycol) monolayer onto which a drug can be linked. Gold nanoparticles have been loaded with doxorubicin [82] and oxaliplatin [75]. In both cases, a high cellular uptake was observed along with improved or at least similar cytotoxicity to that of the free drug.

10.7.2.1 ICP-MS and Gold. Gold is monoisotopic (^{197}Au), and because of its high first ionization potential, the degree of ionization in the argon plasma is low (51%). But since polyatomic interferences of m/z 197 are virtually nonexistent when analyzing biological samples and the complete Au signal is seen on one isotope, instrument detection limits in the 1–3 ng/L range can still be achieved. However, one important prerequisite is to ensure that Au is in a soluble form during the sample preparation processes (e.g., as the $[\text{AuCl}_6]^{3-}$ ion) to prevent reduction and precipitation of solid Au particles. Furthermore, Au drugs are often lipophilic and are easily reduced to metallic Au, making sample preparation and ICP-MS analysis a challenge. As a consequence, very few studies on the application of ICP-MS for investigation of Au-containing drugs have been published. One exception is the study by Zhao *et al.* [83], who used LC-ICP-MS to determine Au-containing metabolites in urine sample from patients treated with myocrisin and auranofin, the main metabolite found was $[\text{Au}(\text{CN})_2]^-$. Surprisingly, new studies on the application of ICP-MS technology in the investigation of Au-containing drugs have not been published in the last 10 years, but the new interest in the application of Au nanoparticles as drug-delivery vehicles may prompt a renewed interest in the use of ICP-MS for analysis of gold-containing drugs (Table 10.5).

Abbreviations: FIA, flow injection analysis; RBCs, red blood cells; WAX, weak anion exchange; SEC, size exclusion chromatography.

10.7.3 Ruthenium

In recent years, there has been a growing interest in ruthenium complexes as anticancer drugs. Two Ru(III) drugs with octahedral coordination chemistry, NAMI-A (imidazole Ru(III) dimethyl sulfoxide complex) and KP1019 (indazolium[transtetrachlorobis(1H-indazole)ruthenate(III)]), have successfully completed phase I clinical trials. NAMI-A showed efficacy as an antimetastatic agent, whereas KP1019 exhibited activity against colorectal carcinomas and primary human tumors. Other ruthenium complexes that exhibit favorable pharmacological profiles are under investigation, for example, RAPTA complexes that are ruthenium(II)-arene complexes bearing the 1,3,5-triaza-7-phosphatricyclo[3.3.1.1]decane ligand, the structures are shown in Fig. 10.4. Ruthenium binds strongly to DNA by mechanisms similar to the ones proposed for Pt(II) complexes. Protein binding is supposed to play a role in the mechanism of action, as Ru(III) uptake by cells is mediated by transferrin transport. This transport mechanism offers opportunities to deliver not only Fe but also Ru complexes inside the cancer cells improving tumor selectivity [86]. Ruthenium(II)-chloroquine complexes have recently been shown to be potential antimalaria drugs [87].

10.7.3.1 ICP-MS and Ruthenium. Ruthenium has seven stable isotopes ^{96}Ru , ^{98}Ru , ^{99}Ru , ^{100}Ru , ^{101}Ru , ^{102}Ru , and ^{104}Ru , the latter three being the most abundant with abundances of 17.1%, 31.6%, and 18.6%, respectively. Ruthenium is almost fully ionized (96%) in the argon plasma. Potential interferences are few, but since most originate from matrix elements (e.g., $^{40}\text{Ar}^{61}\text{Ni}^+$, $^{64}\text{Ni}^{37}\text{Cl}^+$, and $^{85}\text{Rb}^{16}\text{O}^+$ on $^{101}\text{Ru}^+$ and $^{62}\text{Ni}^{40}\text{Ar}^+$, $^{66}\text{Zn}^{36}\text{Ar}^+$, and $^{65}\text{Cu}^{37}\text{Cl}^+$ on $^{102}\text{Ru}^+$), interferences can be a problem when analyzing biological samples, as transition metals such as Ni, Cu, and Zn often occur in relatively high concentrations. Still, these interferences can often be avoided by the use of multiple Ru isotopes and careful monitoring of transition metal levels during analysis. Detection limits for total determination of Ru in biological samples below 0.1 $\mu\text{g/L}$ can be obtained on a routine basis [10], while detection limits for LC-ICP-MS are in 2–10 $\mu\text{g/L}$ range (Table 10.6) [88].

10.7.3.2 Interaction Studies. The first study on the interaction of a ruthenium-based drug with serum proteins by ICP-MS detection was performed by Szpunar *et al.* [46]. They observed that the ruthenium drug was bound to proteins with a molecular mass of 50–70 kDa. No free drug was observed, as neither the drug nor its hydrolyzed products could be eluted from the column. The same approach was taken by Sulyok *et al.* [88]. They analyzed the drug KP1019 by SEC-ICP-MS and also observed that the ruthenium signal appeared in the 50- to 70-kDa band. By LC-ES-MS, they identified two proteins in the band, HSA and Tf. The stoichiometry of the KP1019 protein binding was determined by the Ru/S ratio. Less than 2% of KP1019, in an incubated mixture of HSA and Tf, was found to bind to Tf. This example illustrates how the multielemental detection feature of ICP-MS provides qualitative as well as quantitative information on the drug–protein binding [88]. Recently, Groessl *et al.* [65] used SEC-ICP-MS to study the interaction of RAPTA complexes with transferrin and found that the affinity was higher for holotransferrin (iron saturated) than for apotransferrin (iron free), suggesting an iron-mediated Ru binding mechanism. Similar results were obtained by examination of the interaction of KP1019 with HSA and Tf using CE-ICP-MS. Hartinger *et al.* [90] developed a two-dimensional chromatographic scheme for studying interactions of KP1019 with serum proteins in plasma samples from a patient by monitoring Ru, ³²S¹⁶O⁺, and ⁵⁶Fe⁺. This study highlights the strength of ICP-MSs multielemental capabilities.

10.7.3.3 Determination of Total Ru in Biological Samples. Brouwers *et al.* [10] successfully developed an ICP-MS method for the determination of Ru in human plasma filtrate, plasma, and urine samples from an NAMI-A phase I clinical trial. Sample preparation was a simple dilution with either 1% HNO₃ or 0.01% EDTA-triton before analysis. Potential polyatomic interferences were avoided by monitoring the ¹⁰²Ru isotope, which was the isotope least affected by interferences. Carefully correcting for the adsorption, an LOD of 0.44 fg Ru per cell was achieved along with good accuracy and precision on repeated cellular uptake experiments. These two studies clearly demonstrate that ICP-MS is a very powerful technique for the determination of Ru in biological samples and that controlled sample preparation is of utmost importance.

The availability of RAPTA complexes linked to recombinant HSA has been investigated with the purpose of exploiting the EPR effect [91].

10.7.4 Other Metal-Containing Drugs

Several other metal complexes have been investigated in search of new drugs. Some of these, such as Gd(III)-, Ga(III)-, and Ti(IV)-complexes, have entered clinical trials. Some of the most prominent examples of potential metal-containing drugs are outlined below and summarized in Table 10.7.

10.7.4.1 Gadolinium. Motexafine gadolinium is a member of the texaphyrins or “expanded porphyrins” class of macromolecules capable of coordinating large metal ions [96]. It has been subject to several clinical trials for its anticancer activity and is also under investigation as a site-directing molecule improving delivery of carboplatin [94,100]. Gadolinium complexes, for example, gadolinium diethylenetriamine pentaacetic acid (Gd-DTPA) are widely used as magnetic resonance imaging (MRI) contrast agents due to gadolinium’s ability to enhance the intracellular ¹H MRI signal. Contrast agents should be nontoxic and excreted rapidly, as they are often given in gram quantities. Gadolinium has seven isotopes, and ICP-MS sensitivity and accuracy are good, provided that potential interferences from various lanthanide oxides are resolved or minimized. ICP-MS has been used to study the pharmacokinetics and biodistribution of motexafin in plasma and tissue [94] and to follow the excretion and stability of Gd-DTPA in urine from a patient, using SEC-ICP-MS. No Gd-DTPA metabolites were found, and the complete dose (> 99%) was excreted within 24 h [95].

10.7.4.2 Gallium. A small group of Ga(III) complexes has entered clinical trials as oral anticancer drugs. One of these was designed to be similar to the iron(III)–maltol complex, which is known to provide iron in a bioavailable, readily absorbable form. These gallium complexes are interesting, as Ga³⁺ is more bioavailable than other metal ions (e.g., Ru³⁺) and allows administration as an oral drug. In the cell, Ga(III) impairs DNA replication leading to apoptosis through the mitochondrial pathway [101].

Gallium has two isotopes, ⁶⁹Ga and ⁷¹Ga. The ICP-MS analysis of gallium is hampered by many polyatomic interferences (various ClO₂⁺ and SO₂⁺ ions) plus interference from doubly-charged ¹³⁸Ba²⁺ ions, which makes accurate determination of total gallium at low levels in biological levels difficult. CE-ICP-MS has been used to investigate the binding of KP46 to plasma proteins. By simultaneous monitoring of ⁶⁹Ga⁺, ³⁴S⁺, and ⁵⁶Fe⁺, it was shown that KP46 preferably binds to transferrin [34].

10.7.4.3 Titanium. The organometallic agent titanocene dichloride [Cp₂TiCl₂] (Fig. 10.4) has entered clinical trials as an anticancer drug [102–104]. To our knowledge, no ICP-MS analysis has been carried out on titanocenes. Titanium analysis using ICP-MS in biological samples is, in general, difficult due to heavy interference from polyatomic ions and isobaric overlap in the mass range of Ti isotopes (⁴⁶Ti, ⁴⁷Ti, ⁴⁸Ti, ⁴⁹Ti, and ⁵⁰Ti); furthermore, careful sample preparation is critical as titanium can be difficult to maintain in solution. As a consequence, there are few papers describing the ICP-MS analysis of Ti in biological samples, one exception is the paper by Sarmiento-Gonzalez *et al.* [98], who studied the binding of Ti(IV) to transferrin in blood serum using LC-ICP-MS.

10.7.4.4 Vanadium, Zinc, Rhodium, and Osmium. Vanadium and zinc complexes have been suggested to be involved in the regulation of glucose level in the body and thereby mimic the biological effects of insulin. Studies on binding of vanadium and zinc to transferrin and other human serum proteins utilizing various hyphenated ICP-MS techniques have been reported [37,97,105]. Like for Ti and Ga, ICP-MS analysis of V and Zn is hampered by a large number of polyatomic interferences and can

be difficult. By applying hyphenated techniques and by careful monitoring of blank levels/contamination, ICP-MS analysis of low levels of V and Zn in biological samples is possible.

Recently, rhodium and osmium analogs to the ruthenium RAPTA drugs have been synthesized, these complexes show similar cytotoxicity in cancer cell lines as that of the Ru RAPTA complexes [106]. However, no ICP-MS studies on these compounds have been reported.

10.8 SUMMARY

ICP-MS is a hard ionization MS technique characterized by a high and structure-independent sensitivity as all MBDs and their metabolites are converted into the M^+ ions in the plasma. When interferences have been overcome by use of collision or reaction cell instruments, instrumental detection limits at the nanogram per liter level are obtained for most metals.

A distinctive feature of MBDs is their interactions with proteins and other biomacromolecules. LC-ICP-MS is the method of choice for analysis of these interactions. The system tolerates well high salt concentrations used in ion-exchange chromatography, while the high organic solvent loads used in RP chromatography is not readily compatible with plasma. This problem is most easily solved by diminishing column dimensions, resulting in lower flow rates of the organic solvent introduced. Microbore and capillary column separations will probably become the method of choice before long.

CE coupling to ICP-MS is not as straightforward as the LC coupling and has not gained a broad use presumably because of the difficulties of hyphenating and the higher LODs than those of LC-ICP-MS. However, as CE offers a complementary separation technique to LC, it still finds applications in certain research areas.

Hyphenated ICP-MS systems have been applied to numerous experiments on elucidation of metal–drug reactions with plasma proteins and DNA, which is a target for several of these drugs. These comprise primarily platinum-containing drug compounds, as cisplatin has been used for decades, and ruthenium and gold are gaining increasing attention as alternative metals in new anticancer agents. The multielement capability of the technique is exploited by simultaneous monitoring of the metal and sulfur to examine protein binding, in general, and simultaneous monitoring of iron or phosphorus to examine binding to the iron-containing transferrin and DNA, respectively. As the interest in MBDs involving a variety of possible metals for different purposes grows rapidly, the use of ICP-MS will increase correspondingly.

ABBREVIATIONS

AEX	Anion Exchange
CE	Capillary Electrophoresis
CIM	Convective Interaction Media
DNA	Deoxyribonucleic Acid
GSH	Glutathione
FIA	Flow Injection Analysis
Hb	Hemoglobin

HILIC	Hydrophilic Interaction Chromatography
HSA	Human Serum Albumin
ICP-MS	Inductively Coupled Plasma Mass Spectrometry
IDA	Isotope Dilution Analysis
IgG	Immunoglobulin G
IP	Ion Pair
LA	Laser Ablation
LC	Liquid Chromatography
MRI	Magnetic Resonance Imaging
MT	Metallothionein
PUF	Plasma Ultrafiltrate
RP	Reversed Phase
RBCs	Red Blood Cells
SEC	Size Exclusion Chromatography
UF	Ultrafiltrate
WAX	Weak Anion Exchange

11.1 SUMMARY

Over the last decade, there has been a steady increase in the number of publications that describe on-line combination of electrochemical (EC) techniques with liquid chromatography-mass spectrometry (EC-LC-MS) [1,2]. These techniques have been shown to possess unique capabilities to both utilize and study oxidative and reductive (redox) reactions. This can provide not only analytical utility (e.g., LC detection) but also an insight that can be beneficial to drug discovery and development processes. This latter capability is largely based on the relevance of redox processes to many chemical and biochemical aspects of drug development, including chemical oxidative degradation [3], oxidative metabolism and formation of reactive species [4,5], and the relevance of oxidative stress in disease and toxicity [6]. The incorporation of rugged commercially available EC cells into the existing LC-MS systems and protocols is typically inexpensive and readily implemented. These and other factors have led to an increased use of these techniques at strategic times within the drug development process.

This chapter is an overview of several EC/LC-MS approaches, specifically those that employ three-electrode EC flow cells for controlled potential electrolysis. We describe some basic theories and a number of applications including those that use EC as reaction devices in series with MS and those involving parallel EC and MS for HPLC detection. Serial EC-MS applications include generating and characterizing products that often correspond to metabolites, degradants, or short-lived species of interest. The

quantitative and qualitative aspects of parallel EC-Array-MS are also described for studying chemical oxidative stability, for profiling metabolites and degradants and for metabolomics. To facilitate expanded adoption of EC/LC-MS techniques, our emphasis is on basic methodology and practical considerations.

11.2 OVERVIEW OF ELECTROCHEMICAL (EC) FLOW CELLS

The common uses of three-electrode EC flow cells include HPLC detection (LCEC) [7–10] and hydrodynamic voltammetry [11]. There are many excellent sources of EC information that can be consulted for detailed description of theory and applications [12–15]. Briefly, the cell functions by establishing a specific applied potential between a reference electrode (RE) and a working electrode (WE). The auxiliary electrode (AE), through electrical feedback via a potentiostat, provides the energy necessary to maintain the potential and relies on solution conductivity (typically mobile phase with ≥ 20 mM buffer) to complete the circuit. This energy drives electrolysis of solution-phase species (i.e., analyte and reactant) at the WE surface. The majority of applications described below involve recording EC cell current and associated mass spectra as a function of, and as a result of, the applied potential.

EC cells with carbon-based WE are the most widely used for LCEC and, as such, are the primary focus of this discussion. Other WE materials (e.g., Au, Ag, and Pt), while more advantageous for certain applications [16,17], are typically more prone to surface passivation and are generally less practical for many solvent and pH conditions [16]. There are several possible EC flow cell designs, but only three basic geometries are in widespread use: thin-layer, wall-jet, and porous flow through. Thin-layer and wall-jet amperometric cells have small surface area WE, and when using typical HPLC flow rates (i.e., 0.2–2.0 mL/min), only a small percentage (typically $<5\%$) of analyte comes into close-enough proximity to the WE to be oxidized or reduced. Response is therefore affected by changes in flow rate, and the overall yield of reaction products is typically low. Also, electrode maintenance is frequently required because of WE passivation, particularly, when analyzing complex matrices or a large number of samples [18]. Thin-layer and wall-jet cells are widely used in the analysis of limited volume samples, such as microdialysis perfusates. In these instances, the combination of low volume EC cells with microbore chromatography can provide limits of detection in the femtogram range. A third class of EC flow cell utilizes high surface area microporous WE to achieve higher electrolysis efficiencies (typically $>95\%$ at 2.0 mL/min). This design is termed *coulometric* since the integrated response (peak area) represents the charge realized (coulombs) from nearly complete electrolysis of analyte as described by Faraday's law. A disadvantage to the coulometric cell design is that the WE is not accessible to mechanical resurfacing. However, in comparison to thin-layer and wall-jet cells, coulometric cells provide higher yield and more reproducible reactions (i.e., response) and require much less maintenance [8–10]. These advantages have led to its more widespread use in the analysis of complex matrices and in higher throughput approaches including those that utilize gradient elution HPLC. Further discussion is focused on two basic implementations of coulometric EC: (i) a single cell upstream and in series with MS and (ii) multiple cells (EC-Array) parallel with MS.

11.3 ELECTROCHEMISTRY IN SERIES WITH LC-MS

11.3.1 General Considerations

Several laboratories have used single EC cells as a simple “add-on” to a typical LC-MS setup. The common experimental configurations (Fig. 11.1) include flow injection, direct infusion, and both pre- and postcolumn EC/LC-MS. Several design aspects must be considered when adding an EC cell to an LC-MS system, such as solution conductivity, electrical grounding, and cell volume. Supporting electrolyte is required to provide solution conductivity. Common LC-MS mobile phases containing, for example, 0.1% formic acid or 5–10 mM ammonium acetate may have insufficient conductivity, and the resulting *IR* drop must be compensated for by using higher applied potentials. While this may be acceptable for some experiments, the use of more conductive solutions is generally preferred. This is particularly important for LCEC detection and for generating hydrodynamic voltammograms (HDVs) where low solution conductivity may lead to poor response, peak tailing, and loss of voltammetric resolution. Volatile buffers (e.g., ammonium acetate or ammonium formate) of at least 20 mM concentration typically provide sufficient conductivity and pH buffering. While higher buffering capacity may provide improved control of chromatography and detection, it is important to consider potential adverse effects on MS detection (e.g., ionization suppression, adduct formation, background noise). A further consideration is related to the use of conductive fluids and high voltage ion sources. The liquid inlet to the ion source (e.g., electrospray) of most LC-MS instruments is electrically grounded. However, in some instruments, there exists the possibility that current flow may occur from the high voltage ion source through a conductive fluid. Since many LC eluents are somewhat conductive, grounding the fluid line is typically recommended, irrespective of the use of EC. Current flow through the fluid line may compromise analyte integrity since it can affect the interfacial potential of distal, upstream, wetted components (e.g., injector and analytical column), which can lead to unwanted redox reactions [19]. A simple way to ground the fluid line is to use a stainless steel fluidic union connected to the ground of the MS high voltage power supply, as previously described [20].

Figure 11.1 Representative serial EC/LC-MS configurations using either an ESA Model 5021A or 5030 coulometric EC cell controlled with Coulochem III for MS Detector (ESA Biosciences, Inc., Chelmsford, MA, USA).

11.3.2 Applications Using Flow Injection Analysis

Serial EC/LC-MS configurations are used in drug discovery and development to study the susceptibility of a compound to oxidation (or reduction), the nature of products and short-lived intermediates, and the associated reaction pathways. These data are used to provide insight to chemical stability, metabolism, and toxicity in a variety of contexts from rapid early-stage screening to more in-depth studies. A common approach is to use flow injection analysis (FIA) for medium throughput analysis of a series of compounds [21]. Each compound is typically analyzed at several EC potentials (e.g., 0, 400, 800, and 1200 mV vs Pd) to quickly (e.g., <30 s per injection) generate voltammetric data, which are indicative of relative ease of EC oxidation. The corresponding MS data are then used to provide information on the likely chemical sites of oxidation and the nature of products. These data are typically generated for analogous series to provide input to lead optimization strategies or to provide structural alerts for oxidatively unstable compounds. It should be noted that instantaneous voltammetric data may also be generated from a single injection by using several EC cells arranged in series, each successive cell maintained at a higher potential than the preceding cell. This technique, typically conducted in early-stage discovery for studying oxidative stability, is discussed in Section 12.4.

11.3.3 Pre- and Postcolumn EC with LC-MS

A logical extension of FIA with serial EC/LC-MS is to incorporate a separation technique to further characterize products. Figure 11.2 is an example of precolumn EC oxidation of tamoxifen. With the EC cell at 600 mV, the total ion chromatogram (TIC) shows two primary peaks corresponding to the starting material (tamoxifen) and, at an earlier retention time, an N-demethylated product. With the precolumn EC cell at 900 mV (Fig. 11.3), additional peaks are evident, including possible aromatic hydroxylation and dealkylation products. This example shows that product formation can, to some extent, be manipulated through simple control of EC cell potential and that several of these EC oxidation products correspond to biological metabolites or degradants of tamoxifen [22]. It should be noted that EC oxidations lack the steric control of enzyme-catalyzed reactions and may also involve different reaction mechanisms (see Section 12.3.6 for additional details). Therefore, the relative abundance of products generated by EC is not expected to correlate with that of biological systems. EC generation of metabolites is thus considered to be a qualitative technique.

The examples in Figs. 11.2 and 11.3 illustrate on-line generation and analysis of EC products using LC-MS conditions that are typical of metabolic studies (e.g., *in vitro* microsomal analysis). Serial EC/LC-MS can thus be used with “neat” parent compound solutions for preliminary optimization of LC and MS conditions for subsequent metabolite analysis in biological samples. By using identical conditions, EC data may then be used as an input to automated metabolite identification software to aid in finding metabolites present in more complex biological matrices [23].

11.3.4 Semipreparative EC Synthesis

When the data from an EC-generated product corresponds to that of a biological metabolite, the EC technique may then be viewed as a selective and rapid synthetic

Figure 11.2 On-line oxidation of tamoxifen (50 μL of 20 $\mu\text{g/mL}$ diluted in mobile phase) using precolumn ESA Model 5021 EC cell (600 mV vs Pd). (a) Total ion chromatogram and (b) full-scan mass spectra of chromatographic peaks labeled A and B. Conditions: binary gradient from 16% to 80% acetonitrile over 10 min, 20 mM ammonium acetate as supporting electrolyte. Shiseido C18MG 3 μm 75 $\times$ 4.6 mm i.d. column, 1 mL/min, 200 $\mu\text{L/min}$ split to MS. Agilent 1100MSD single quad, positive ESI (electrospray ionization), scan 80 to 500 m/z . Fragmentor 70, gain 1.0, threshold 150, step 0.25, drying gas flow 12 L/min, nebulizer pressure 35 psig, drying gas temperature 350°C, and capillary voltage 3500 V.

route to small quantities of this metabolite. This can then be used to facilitate structural elucidation or, more generally, to produce additional chemical entities. Earlier studies demonstrated the feasibility of scaling up on-line EC techniques to produce sufficient quantities for structural confirmation by NMR [24]. Tahara *et al.* [25] have more recently described the EC production in milligram quantities and subsequent structural elucidation of a troglitazone metabolite. By using nonaqueous conditions, Tahara and coworkers [26] furthermore demonstrated the direct EC production of a reactive metabolite of troglitazone, which was useful to investigate its mechanisms of hepatotoxicity. As discussed in the following section, the ability to use a purely instrumental technique to quickly generate EC products can provide significant advantages for studying certain reactive species where nonspecific binding (i.e., interaction with endogenous biochemicals) may prevent detection in biological systems. Madsen *et al.* [27] have also recently described a method for EC synthesis of a glutathione (GSH) conjugate of clozapine, which made it possible to obtain structural information of this potentially toxic species by NMR. Moreover, the recent development of higher capacity coulometric cells (Models 5125 and 5150 Synthesis Cells, ESA, A Dionex Company) provides the ability to produce even larger quantities of material. The simplicity and speed of on-line EC/LC-MS may therefore provide an effective means of characterizing some of the many unknown metabolites, including reactive species, encountered in multivariate profiling studies.

Figure 11.3 On-line oxidation of tamoxifen with precolumn EC cell at 900 mV versus Pd. Remaining conditions are as in Fig. 11.2. (a) Total ion chromatogram and (b) full-scan mass spectra of chromatographic peaks labeled A through E.

11.3.5 EC Generation and Analysis of Reactive Intermediates

Many studies suggest that redox metabolism of a wide range of chemical structures leads to the formation of reactive electrophiles that participate in a diverse array of toxic processes that typically involve covalent binding or other modifications to small and large molecules (e.g., DNA, proteins, peptides, and lipids), redox cycling, antioxidant/scavenger depletion, and other elements of oxidative stress [4–28]. The propensity of compounds to undergo redox-based metabolic activation to form reactive electrophilic species is therefore a major consideration in pharmaceutical development [29,30]. The topic of bioactivation and reactive metabolite assays is further discussed in the chapter titled *Bioactivation and Reactive Metabolite Assays* of this volume. Several reports have shown EC/LC-MS useful in the

study of reactive intermediate metabolites [21–35]. A variety of experimental configurations have been described that incorporate a nucleophilic trapping agent (typically, GSH), by either coinjection or infusion, with FIA, precolumn EC, or postcolumn EC. Lohmann *et al.* [36] have recently described EC simulation of the oxidative metabolism of paracetamol, amodiaquine, and clozapine. Interestingly, by using a reaction coil between the EC cell and HPLC injector, they were able to demonstrate adduct formation of the reactive metabolites with the proteins β -lactoglobulin A and human serum albumin. The formed drug–protein adducts were characterized with on-line time-of-flight MS, and the modification site was localized using FTICR-MS (Fourier transform ion cyclotron resonance-mass spectrometry). The authors describe this approach as a simple and fast method for the rapid risk assessment of covalent protein binding as well as for the synthesis of covalent drug–protein adducts in high purity and high yield. FIA and precolumn EC have been used to analyze neat drug solutions in order to investigate the susceptibility of a parent drug to EC oxidation, to characterize the reactive intermediates formed, and to study the chromatographic and MS behavior of trapped species. Postcolumn configurations have also been used to analyze biological (microsomal) preparations to investigate individual metabolite susceptibility to EC oxidation and to identify which metabolites form reactive species.

Figure 11.4 provides a basic example of precolumn EC oxidation using the widely studied compound, acetaminophen (APAP). Oxidative metabolic activation of APAP to form *N*-acetyl-*p*-benzoquinoneimine (NAPQI) is widely regarded as an essential component of its hepatotoxic effects in humans [5]. MS data indicate that EC oxidation of APAP in the presence of GSH (coinjected) resulted in two separate peaks corresponding to monogluthathionyl conjugates and one peak indicative of a digluthathionyl conjugate. These results are comparable to those reported nearly two decades ago by Getek and colleagues [31] using coulometric EC cells with thermospray MS. Several other “model” compounds have been studied using these techniques, including 4-aminophenol, BHT (butylated hydroxytoluene), estradiol and metabolites, phenacetin

Figure 11.4 Precolumn oxidation of APAP with GSH as trapping agent. 10 μ L of 20 μ g/mL APAP, 1 mM GSH mixture with precolumn ESA Model 5021 cell at 500 mV versus Pd. Binary gradient elution from 1% to 80% acetonitrile (ACN) in 5 min, 20 mM ammonium acetate as supporting electrolyte. Shiseido C18 MG 3 μ m 50 $\times$ 4.6 mm i.d. column, 1 mL/min, 200 μ L/min split to MS. MS conditions are as in Fig. 11.3, except scan range that is 80–1000 m/z .

Figure 11.5 Precolumn oxidation of phenacetin. Conditions are as in Fig. 11.2, except LC detector that was an eight-channel EC-Array (CoulArray, ESA Biosciences, Inc., Chelmsford, MA, USA) with Model 6210 EC cell potentials of 0–840 mV versus Pd in 120-mV increments.

[21], and clozapine [33]. While the products expected from the known systems are generally formed and can be interrogated to reveal structural information, the EC oxidation sometimes results in a wide array of oxidation products not always seen in biological systems. It has been recognized that nonmicrosomal and nonenzymatic redox reactions may play a role in toxic processes [37], and further study is required to assess the significance of these observations. These data do, however, highlight the usefulness of EC/LC-MS as a rapid and efficient means of generating trapped products of reactive intermediates for structural characterization by LC-MS/MS from both parent drug and *in vitro* metabolites.

Figure 11.5 illustrates the precolumn oxidation of a phenacetin solution with LC-EC-Array detection (discussed in more detail in the following section). A peak, which eluted at 3.8 min, shows a characteristic voltammetric profile (i.e., reduction followed by oxidation) of a quinone species. On the basis of EC-Array and MS data (not shown), this peak has been identified as NAPQI, the expected reactive intermediate. This peak was not evident in a microsomal incubate of phenacetin analyzed using the same conditions (not shown). A possible explanation for this is that nonspecific binding of this reactive species occurred in the biological preparation. Thus, an additional advantage to the use of on-line EC/LC-MS includes the ability to examine short-lived species that, although potentially relevant, may not as readily be observed in biological systems. Many other pharmaceutically relevant applications of EC-MS have been described and are beyond the scope of this discussion. These applications include EC derivatization to enhance MS ionization [38], mass tagging [39], and protein cleavage techniques, several of them are discussed in a recent focus issue on EC combined with MS [1].

11.3.6 EC “Mimicry” of Metabolism

There are many examples, as above, which have demonstrated that the EC oxidation products for a given compound often coincide with metabolites observed in biological assays [31–33,40–42]. These and other EC oxidation products may also be observed in purposeful degradation or stability studies. It must be recognized, however, that

enzyme-catalyzed, chemical, and EC oxidations are often very complex and involve different phenomena. Studies conducted by Jurva and colleagues [43,44] provide very useful insight into the mechanistic aspects of EC and enzymatic oxidative reaction pathways, particularly in the context of cytochrome P450 (CYP450) metabolism. They have shown that EC oxidation using porous carbon WE generally leads to the formation of similar products in those enzyme-catalyzed reactions that are supposed to proceed through a mechanism initiated by a one-electron transfer oxidation. Examples of CYP450 reactions mimicked by carbon-based WE include dehydrogenation, N-deacetylation, N-dealkylation, S-oxidation, and aromatic O-dealkylation. Reactions initiated by H-atom abstraction, such as aliphatic C-oxidation and hydroxylation of aromatic rings without electron-donating groups, are, however, generally not mimicked by EC oxidation. There are several examples of alternative or modified WE materials and reaction conditions to affect specific reactions. This includes the immobilization of enzymes [45] and biomimetic redox indicators [46] on solid electrodes and solution-phase conditions such as those described for EC-assisted Fenton reactions [47]. Johansson *et al.* [48] and Lohmann and Karst [49] have recently studied the extent to which EC oxidation, electrochemically assisted Fenton chemistry, and synthetic metalloporphyrins can be used in combination to mimic a large range of CYP450-catalyzed oxidations. While these approaches are extremely useful for many applications, EC is generally considered to be a complement to, rather than a substitute for, a given *in vitro* assay. A similar argument applies to chemical oxidative degradation studies, which are discussed in a later section.

11.4 EC-ARRAY TECHNIQUES

11.4.1 General Considerations

The general concepts of EC-Array are described in detail elsewhere [7,50]. Briefly, this technique employs up to 16 series EC cells (Fig. 11.6) with porous graphitic carbon-based WE, similar in concept to those described in the previous section. Each cell is typically poised at a different fixed potential, thereby spanning a wide potential window to allow detection of a broad scope of redox-active analytes during the transit of a single injected aliquot through the cells. Efficient electrolysis obtained with high surface area coulometric WE allows for selective detection and resolution of coeluting analytes, on the basis of differences in their relative ease of oxidation and/or reduction. Stated differently, each analyte in a coeluting band will demonstrate signal dominance

Figure 11.6 Representative configuration of LC with postcolumn flow passively split to EC-Array and MS. Model 6210 EC cells were controlled with a 16-channel CoulArray (ESA Biosciences, Inc., Chelmsford, MA, USA). *Source:* Reprinted from Ref. 75 by permission of Elsevier, Inc.

on a different WE based on their relative ease of oxidation or reduction. In general, EC reactions are typically observed according to the following general rank order (by relative ease of oxidation): *o*, *p*-quinol and *o*, *p*-aminophenol > tertiary amine < *m*-quinol $\approx$ phenol $\approx$ arylamine > secondary amine $\approx$ thiol > thioether $\neq$ primary amines and aliphatic alcohols. HDVs for each redox-active metabolite are obtained from the response across adjacent EC-Array sensors. These data are a reflection of the kinetic and thermodynamic components of electron-transfer reactions. Since chemical structure is a critical determinant of an analyte's redox behavior, the intrinsic generation of an HDV with EC-Array provides qualitative information for each species.

11.4.2 Applications Using Flow Injection Analysis

The use of FIA with a single EC cell in series with MS was described above to study compound susceptibility to oxidation. This requires multiple injections for each compound. An alternative approach is to use EC-Array (without MS) to generate voltammetric data from a single injection. This has the advantage of providing higher throughput but lacks the structure–activity and product information provided by MS. MS is not used downstream of EC-Array since the products that are selectively formed at upstream electrodes may further react at downstream electrodes, thus preventing their detection by MS. Many laboratories use EC-Array to generate voltammetric data to study oxidative stability, largely based on the pioneering work of Lombardo and Campus [51]. Chemical oxidation, a common mode of degradation for active compounds and drug products [3], is a significant concern at all stages of drug discovery and development. The relative tendency for compounds to undergo chemical oxidative degradation via electron-transfer mechanisms is closely related to their EC redox potentials [3]. As described in the previous section, oxidation reactions are often complex phenomena with a variety of mechanisms not necessarily modeled by a given EC technique. EC is typically used as part of a suite of techniques (e.g., oxygen/radical initiator, photolytic) for comprehensive study.

Representative data from FIA with 16-channel EC-Array detection is shown in Fig. 11.7. Using the described conditions, voltammetric data obtained for several model

Figure 11.7 Voltammetric plots for seven model compounds representing normalized cumulative peak area. Dashed lines correspond to those compounds reported as oxidatively unstable; solid lines are indicative of oxidative stability.

compounds demonstrated that the most stable compounds oxidized at the highest potentials, while the least stable compounds oxidized at the lowest potentials [52]. While FIA was suitable for this pilot study, the approach was found to be inadequate for high throughput library-stage screening, particularly when considering the possible presence of electroactive impurities. Therefore, Lombardo and Campus [51] developed chromatographic methodology that used a short (3 cm) C18 column and isocratic elution in a strong (90% organic) eluent. This together with the inherent selectivity of EC-Array and the appropriate choice of signal threshold has allowed the generation of voltammetric data with a typical throughput of eight 96-well plates per week per instrument. This work, now applied to more than 30,000 compounds, was used to develop alerts for oxidatively unstable compounds, thus reducing the potential for later-stage issues. Furthermore, there are several additional potential uses of this approach, which are currently under investigation. These uses include the ability to assess the potential for degradation on library storage, to develop predictive structure–stability relationships, and to examine excipient compatibility. Webster *et al.* [53] have recently described the use of this technique in antioxidant selection for pharmaceutical formulations.

11.4.3 Quantitative Bioanalysis of Complex Matrices

The more traditional use of EC-Array is with LC separation for multicomponent quantitative and qualitative analyses. The primary advantages of this technique include two-dimensional (i.e., chromatographic and voltammetric) resolution, femtomole sensitivity, and data-dependent acquisition (autoranging), which facilitates use with gradient elution and provides a 10^5 dynamic response range [50,54]. LC-EC-Array has been widely used for routine analysis of redox-active substances with primary *in vivo* application to clinical chemistry [50,55,56], neurochemistry [57–59], and redox biochemistry [60–66]. Many pharmaceutical laboratories have adopted EC-Array for LC analysis of degradants and metabolites (i.e., related substances). A majority (estimated >85%) [67] of pharmacologically active small molecules possess one or more “EC-active” moieties (see above). The sensitivity (typically 10- to 1000-fold greater than UV–vis absorbance detection) [50,54], selectivity, and qualitative information obtained can provide significant advantages for a variety of applications. There are many examples of the use of EC-Array, specifically for bioavailability and pharmacokinetic studies [68–74]. The coupling of EC-Array as a parallel detector with MS is a logical extension of these approaches and is discussed below.

11.4.4 Metabolomics—Use of EC-Array in Parallel with MS

A major aspect of our recent work has been to couple EC-Array as a parallel detector with MS for metabolomic studies [75]. The comprehensive study of small molecules in living systems, that is, metabolomics, has several challenges, including analyte number and diversity, range of concentrations, and complexity of sample matrices. A variety of techniques exist that are each effective in studying certain classes of molecules within well-delineated concentration ranges; however, no one technique can overcome all the field’s inherent challenges. For instance, NMR is able to detect any molecule that contains an active nuclide (e.g., ^1H and ^{13}C); however, its detection is limited to microgram quantities and does not apply to certain functional groups such as amines and sulfates. MS is very versatile but relies on the ionizability of the compound. EC techniques,

specifically EC-Array, are extremely sensitive detectors of redox-active compounds that, in many instances, are not observed with MS. The parallel use of EC and MS provides the capability to obtain more information from a given metabolite and to extend the number of metabolites and range of chemical classes that can be effectively studied.

A representative chromatogram of rat urine analyzed by parallel EC-Array-MS is shown in Fig. 11.8. As expected, the MS base peak chromatogram shows relatively few, directly visible, metabolite peaks. Mass spectral data from full-scan exploratory studies are typically processed by extracting discrete signals each defined by a particular retention time and m/z and using algorithms to help distinguish analytical

Figure 11.8 (a) MS base peak chromatogram labeled with base peak m/z , and (b) EC-Array multichannel chromatogram (11 of 16 channels shown for clarity). Analytical conditions: 20 μL of 10-fold diluted urine. Gradient elution 1–100% aqueous acetonitrile with 10 mM ammonium formate and 50 mM formic acid; flow rate 1.5 mL/min; Shiseido C18, 3 mm, 75 mm $\times$ 4.6 mm i.d. column; and 4:1 passive postcolumn flow split to EC-Array/MS. EC-Array potentials 0–1050 mV in increments of 70 mV. ESI positive mode, capillary voltage 3500 V, fragmentor voltage 70 V scan range m/z 50–850, and scan speed 1.2 s per cycle. *Source*: Reprinted from Ref. 75 by permission of Elsevier, Inc.

signal from background noise [76]. The resulting data, often consisting of hundreds of discrete signals, are then typically processed by chemometric techniques such as principle component analysis (PCA). Chromatographic variability, ionization suppression, adduct formation and in-source oxidation with MS, and electrode adsorptive and other non-Faradaic processes with EC are important complicating factors to consider in these multivariate analyses. Also, as evidenced in Fig. 11.8, a significant challenge in metabolomics studies is to identify the many unknown peaks that are often observed in a typical biological sample. Our data show that the concurrent acquisition of EC-Array and MS data for each metabolite peak helps to address these potential issues. For example, the observation of a particular redox-active metabolite peak allows the analyst to conduct a more informed and targeted interrogation of the corresponding MS data. Furthermore, specific MS data are useful to normalize for retention time variability observed with both MS and EC-Array data. In addition, our results indicate that many redox-active urinary metabolites exist as solution-phase neutral species under a variety of reversed-phase chromatographic conditions; for example, peaks annotated in Fig. 11.8 are ascorbic acid (AA), uric acid (UA), 5-hydroxyindoleacetic acid (5HIAA), and homovanillic acid (HVA). Of these metabolites, only UA was detected from extracted ion chromatograms (above baseline noise) as its protonated or adducted molecule [e.g., $M + X$ ($X = H^+, Na^+, K^+, NH_4^+$)]. The combined detection scope of MS and EC-Array thus provided higher coverage in a single analysis of the wide dynamic range and broad chemical diversity of urinary metabolites.

In a model study of APAP-induced hepatotoxicity, results from PCA of EC-Array data showed consistent differentiation between experimental groups of animals receiving high dose APAP (200 or 300 mg/kg, 0–8 h collection), low dose (20 mg/kg) APAP, high dose (200 mg/kg) acetylsalicylic acid, and controls. Figure 11.9 shows some of the individual redox-active components that, as indicated from PCA, largely contributed to the observed differentiation. This includes both endogenous (E1–E4) and xenobiotic (M1, M3, and M4) metabolites. These data further demonstrate the complementary nature of EC and MS detection. For example, MS data, along with prior knowledge of a parent compound's analytical behavior and informed prediction of biotransformations, was used to distinguish xenobiotic and endogenous metabolites. This allowed more direct study of changes in endogenous metabolite profiles by PCA. Also, EC-Array data showed clear evidence of an APAP metabolite that was not detected by MS (peak M1). Furthermore, MS data indicated that the peak M3 consisted of two major components having m/z 313 and 232. These m/z values are consistent with the commonly observed O-sulfated metabolite and the less frequently observed mercapturic acid metabolite of APAP, respectively. The similarity in voltammetric response between parental APAP and the peak corresponding to m/z 232 suggests that the easily oxidized 4-amidophenol group is intact. These data are consistent with the commonly observed ring thioether metabolites associated with high dose APAP [77]. Since APAP-mercapturate is a recognized marker of the so-called toxic pathway of APAP, the described approach of exploratory multivariate analysis and targeted interrogation of EC and MS data were an efficient and effective way to determine relevant changes associated with high dose APAP toxicity and to provide insight into the chemical identification of potential biomarkers. These results demonstrate that the combined use of EC-Array and MS may provide significant advantages over either individual technique in addressing the complex nature of metabolomic studies.

Figure 11.9 Overlay of EC-Array data from urine of rats administered (i.p.) vehicle 20 mg/kg or APAP 300 mg/kg ($n = 5$ in each group). Peaks labeled E indicate endogenous metabolites, while peaks labeled M indicate drug metabolites. Base peak m/z ratios as determined from corresponding MS data are shown. APAP-M + S indicates coelution of sulfate and mercapturate metabolites of APAP. *Source:* Reprinted from Ref. 75 by permission of Elsevier, Inc.

11.5 CONCLUSION

EC cells may be combined with LC-MS in a variety of experimental configurations that provide analytical utility and insight into drug discovery and development. This includes their use as reaction devices in series with MS for studies relevant to oxidative metabolism, degradation, and reactive species formation. EC-Array in parallel with MS provides the capability to increase the detection scope of LC-based multivariate profiling with high sensitivity, selectivity, wide dynamic range, and complementary qualitative data. The usefulness of these hyphenated techniques and the data generated for drug discovery and development are largely dependent on the challenges of a particular program and should be enhanced by their informed strategic implementation.

12.1 SUMMARY

The importance of a detailed understanding of drug metabolism for maximizing safety and differentiation has encouraged the development of numerous analytical tools including approaches based on liquid chromatography-mass spectrometry (LC-MS) and nuclear magnetic resonance (NMR). The former is the front-line tool for drug metabolism because of its sensitivity and ability to readily characterize structural changes in multiple molecules in real time as they are separately eluted off the LC column. Localization of metabolic modification can be achieved through designed fragmentation such as provided by MSⁿ experiments. Complementary information provided by NMR is required when the precise localization of sites of metabolism is necessary and when they cannot be assessed through MS-based experiments, a situation that is not uncommon. This chapter provides an overview of the specific

structural information that NMR can provide on drug metabolites in solution, such as sites of modification at the atomic level, regio- and stereoisomer characterization, and dynamic physical properties, and how these parameters are measured. Throughout, the complementarity of NMR-derived information with that provided by LC-MS experiments is pointed out. Limitations and costs associated with NMR are discussed in some detail as are considerations for ideal NMR equipment for drug metabolism studies, including a discussion of hyphenated methods such as LC-NMR. NMR is nonselective, and hence the importance of sample preparation for NMR cannot be underestimated and some attention is given to this topic. Somewhat different approaches required in discovery and development applications are discussed and illustrated through many examples in separate sections and finally a brief discussion of stereochemical measurement by NMR is provided.

12.2 INTRODUCTION

From the earliest structure–activity relationships (SARs) in discovery through the latest phases of clinical development, detailed knowledge of how a drug molecule is transformed by the body is crucial for ensuring that the most effective and safest pharmaceutical agents are brought to the patient. The quest for this knowledge has encouraged the advancement of numerous analytical fields and challenged modern biotransformation scientists to also be multifaceted technology experts [1]. Currently, the most popular tool is, and will likely be for the foreseeable future, high performance liquid chromatography coupled to a mass spectrometric detector (HPLC-MS or LC-MS). Mass spectrometry is, of course, a logical tool for studying biotransformation, as most metabolic modifications involve a change in the mass of a parent molecule, and powerful LC-MS configurations are available at moderate cost. However, unfortunately, a change in mass is frequently not sufficient for identifying the exact location of the metabolic modification and, unless appropriate standards are available, LC-MS is difficult to use quantitatively. This is where NMR steps in. NMR spectroscopy is a quantitative, nondestructive technique that provides atomic resolution information about chemical modifications and conformational changes on molecules in solution, thereby providing exactly the information that is required to fill this gap. As a result, NMR has become invaluable for drug metabolism studies, along with many other pharmaceutical research applications. Although NMR's utility in drug metabolism was recognized early (see the short review article [2] and references therein), the relative insensitivity of the method limited its utility to abundant metabolites. In the past three decades, however, advances in NMR technology have slashed sample requirements from hundreds of milligrams to submicrogram levels, availing the technique to a much broader range of biologically interesting applications, including the ability to resolve complex structural modifications that result from an organism's attempt to eliminate foreign molecules through biotransformation. NMR is the only technique able to routinely identify the exact atom in a molecule that is modified through metabolism. Although its utility is still hampered by poor sensitivity relative to many other analytical techniques, the usefulness of NMR is evidenced by its widespread use. When one does a literature search on "NMR and drug metabolism" over 4000 hits are recorded, going back as far as 1968, and maintaining a steady level over the past 30 years (Fig. 12.1). A limited number of reviews have been published on the use of NMR

Figure 12.1 Annual publications related to the use of NMR in drug metabolism. Bars represent the number of hits returned by searching www.scopus.com using the query: ‘[(“drug metabolism” OR biotransformation) AND (NMR OR “nuclear magnetic resonance”) AND NOT (microbial OR microbiotic OR bacterial)]’ against abstracts, titles, and keywords.

in the context of drug metabolism including reviews that are general in nature [3,4], those aimed at hyphenated NMR techniques [5] and with regulatory focus [6,7]. The basic principles of NMR in the context of metabolite analysis have also been reviewed [8,9]. In this chapter, we provide a background on NMR spectroscopy aimed at those not intimately familiar with it, discuss types of NMR experiments most useful in drug metabolism studies and criteria for when to include them, discuss the strengths and weaknesses of the technique vis-à-vis other analytical approaches (especially hyphenated mass spectrometric techniques), and provide specific examples of its utility from the literature and our own laboratories.

12.3 NMR SPECTROSCOPY—THE GOOD, THE BAD, AND THE UGLY

NMR spectroscopy is the most powerful analytical technique for providing atomic level structural and dynamic information on complex molecules in solution. There are a number of readily obtainable parameters that make NMR spectroscopy such a useful tool for the study of drug metabolites. These parameters include the chemical shift, scalar (through-bond) coupling, dipolar (through-space) couplings, intensity, and relaxation properties. Nevertheless, there are some limitations to NMR, both moderate and severe, that need to be considered when assessing its applicability to any particular study. These strengths and weaknesses are discussed in this section.

12.3.1 The Good

The frequency at which a particular atomic nucleus resonates, or chemical shift, is expressed in parts per million (ppm) with respect to the nucleus’s resonant frequency, ω_0 , and is dependent on the applied magnetic field (see below) as well as the nucleus

Figure 12.2 The 500-MHz NMR spectrum of 10-mM 3-nitrotyrosine dissolved in 66-mM sodium phosphate buffer, pH 7.4. The buffer contains 0.33-mM trimethylsilyl [2,2,3,3- $^2\text{H}_4$] propionic acid sodium salt (TSP) as an internal chemical shift standard. Labels assign specific protons in the molecule to specific NMR signals in the spectrum. In aqueous solvents, the amino and carboxylate protons are generally exchange-broadened and not observed. Inset: expansion of the 500-MHz ^1H NMR spectrum of 3-nitrotyrosine showing J-coupling splitting patterns in the aliphatic region. The superscript denotes the number of bonds between the coupled nuclei. Note that the different magnitudes for the three-bond couplings is a direct result of differential orbital overlap (and hence geometry) between the methine proton (a) and the two magnetically nonequivalent prochiral methylene protons (b, b'). *Source:* Reproduced from Ref. 9 with the permission of Informa Medical and Pharmaceutical Science Books.

under investigation and the electron clouds that surround it. Thus, the exact nature of the chemical bonds and nonbonded interactions that are experienced by an NMR-active nucleus within an atom will contribute to its characteristic chemical shift. If we take nitrotyrosine (the product of the endogenous amino acid and reactive nitrogen species) as an example, each nonexchangeable hydrogen nucleus (proton) will have a unique chemical shift, see Fig. 12.2. This results in a distinctive NMR fingerprint for virtually every molecule, including geometric isomers of the same molecule. Because the nucleus is shielded from the bulk environment, the NMR chemical shift is largely (although not entirely) insensitive to the surrounding analytical matrix. Hence, while changes in the matrix can cause small perturbations to an atom's chemical shift, metabolic modifications that change the nature of the chemical bonds, such as oxidation, have profound and interpretable effects. Since ionization state has a large influence on the electronic environment local to the ionized atom, the pH dependence of chemical shifts, or changes thereto, is also useful for characterizing biotransformational changes in a molecule. For example, a metabolite of cinafloxacin known to be a glucuronide based

Figure 12.3 The use of pH dependence of NMR chemical shifts to evaluate site of glucuronidation in clinafloxacin. Downfield region of the 500-MHz NMR spectrum shows the clinafloxacin H2, H5, and anomeric glucuronide protons. From top to bottom: Clinafloxacin, pH 6.2; clinafloxacin, pH 1.8; clinafloxacin glucuronide, pH 7.8; and clinafloxacin glucuronide, pH 2.0. In clinafloxacin, the changes in chemical shift for H2 and H5 result from ionization of the carboxylate group. The absence of pH dependent shifts in the glucuronide is evidence that the carboxylate is the site of conjugation, rather than the amine.

on LC-MS data was shown to be conjugated on the carboxylate group and not the amino group based on the observation that aromatic protons the carboxyl group were pH independent between pH 7 and 2, indicating that the acid moiety was blocked by glucuronidation (Fig. 12.3) [10].

Scalar coupling arises from cross talk between NMR-active nuclei through shared circulating electrons in overlapping atomic orbitals. Such interactions generally occur over two to three bonds (rarely more than five bonds) and result in a splitting of coupled NMR resonances as illustrated in the nitrotyrosine example (see inset, Fig. 12.2). This “J-coupling” varies with the extent of overlap of the electron orbitals and is therefore highly dependent on molecular geometry. This fine structure within the spectrum makes each NMR molecular fingerprint even more unique than on the basis of chemical shift alone. An additional internuclear interaction phenomenon is dipolar coupling, and it is manifested through the direct mutual influence of proximal nuclear dipoles. Since it is not mediated by electron density and the magnitude of the interaction is inversely proportional to the inverse of sixth power of the distance between the dipoles, this parameter can provide internuclear distance information through the nuclear Overhauser effect (NOE) even in atoms that are far removed from each other in a structure or are

not in the same molecule at all [11]. Both of these coupling phenomena form the basis for numerous powerful two-dimensional (2D) experiments, which are discussed below.

The NMR phenomenon lends itself to quantitative analysis. The integrated NMR signal area, I_x , is proportional to the number of nuclei generating the measured signal, N_x and is given by

$$I_x = k_S N_x \quad (12.1)$$

where k_S is a factor that consists only of parameters associated with the instrument, the nuclear gyromagnetic ratio (γ , a constant characteristic of each nucleus) and the applied static magnetic field, B_0 [12]. Since the k_S is the same for all like nuclei in a given sample, the NMR signal intensity is linear, directly proportional to the concentration over many orders of magnitude and independent of matrix or molecular characteristics. This differentiates NMR from many other spectroscopic and spectrometric techniques where response is strongly influenced by the constitution of the sample and needs to be empirically evaluated for each analyte and set of conditions. As such, NMR is nonselective, and to a first approximation, anything in the sample above the limit of detection with an NMR-active nucleus on it will be observed. If the experimental parameters are selected appropriately, then I_x is directly proportional to the absolute concentration of the molecule in the sample, a property that has led to the development of so-called quantitative nuclear magnetic resonance or qNMR [13] and which can be utilized to positive end in drug metabolism studies [6] without the use of radioisotopes.

Finally, NMR can provide dynamical information on molecular diffusion, conformational exchange, orientational correlation times, and intermolecular interactions in solution. In terms of the relevance of these to drug metabolism studies, qualitative information about metabolism-induced perturbations to molecular geometry can be obtained. For example, hydroxylation of a cyclohexane ring can stabilize or destabilize the internal conformational energetics of the ring, resulting in a measurable effect on the cyclohexane NMR peak shape (and chemical shift), which can then be interpreted in a structural context [14]. As molecular correlation times increase, more efficient relaxation mechanisms lead to line broadening, an effect that is roughly proportional to the molecular weight. Thus, when small molecules, such as drug metabolites, bind to large ones, such as proteins, the relaxation and line width depend on the binding kinetics and the size of the macromolecule. This phenomenon has been used to characterize protein binding and has been applied to CYP450 SAR [15] and sialic acid biosynthesis [16].

12.3.2 The Bad

Even with the highest available magnetic fields, NMR spectroscopy suffers from having only a very small percentage of nuclear spins are in the low energy state relative to the high energy state, that is, a very low Boltzman distribution. The net result of this is that NMR is an extremely insensitive technique relative to many other analytical methods. While LC-MS can, under favorable conditions, detect femtomoles of a given analyte, even the most modern NMR equipment requires several nanomoles of material for analysis in reasonable times. Virtually all modern high resolution NMR spectrometers are pulsed Fourier transform instruments that simultaneously excite all nuclei of a given type and collect raw data in the form of a free induction decay (FID) as they relax back

to ground state (typically within a few seconds). This makes it possible to add together multiple FID transients to improve the spectrum signal-to-noise ratio (S/N), since the signals will co-add and the noise will only increase in proportion to the square root of the number of scans [17]. The S/N therefore improves with the square root of the number of scans. Such signal averaging is always necessary in drug metabolism studies and typically from a few dozen up to several thousand transients must be summed to achieve necessary S/Ns. Thus, poor sensitivity has been (and will continue to be) the Achilles heel of bioanalytical uses of NMR and increasing NMR sensitivity has been the focus of most of the technical developments that have occurred over the past four decades. Over this time, the availability of increasing powerful magnets has been driven by the proportionality between S/N and $B_0^{3/2}$ (factored into Eq. 12.1). As a matter of convention, magnet field strength is customarily expressed as the frequency at which protons resonate:

$$\omega_{\text{OH}} = \gamma_{\text{H}} B_0 \quad (12.2)$$

For example, a 14-T magnet corresponds to a proton field strength of 600 MHz. Increased resolution is another benefit to higher magnetic fields and is proportional to B_0 . Another major improvement in sensitivity was realized near the turn of this century with the development of NMR probes that have cryogenically cooled receiver coils and/or preamplifiers. These so-called cryoprobes achieve their high sensitivity by significantly reducing thermal noise contributions from these components and offer improvements so significant that they are almost considered required equipment for sample-limited work.

Confounding NMR's low intrinsic sensitivity is its nonselectivity. What was mentioned as an advantage above can also be a nuisance. Scarce metabolites, although above the limit of detection, may be fully or partially obscured by interfering components in the sample, which are present at similar or higher concentrations. These can include contaminants arising from the isolation matrixes, other molecules that coisolate, solvents, buffers, and so on, all of which can obstruct important regions of the NMR spectrum. Of course, chemically equivalent nuclei in different molecules, as in the case of enantiomers, or nuclei that are coincidentally magnetically equivalent will be indistinguishable, and conditions must be manipulated to tease apart differences in such cases. Some of these procedures are described below.

12.3.3 The Ugly

All of the tremendous advantages outlined above for NMR spectroscopy do not come without a price. An ideally equipped modern 600-MHz NMR spectrometer with all of the accessories necessary to carry out drug metabolism studies will, as of the time of this writing, cost ~\$1.3 million. Upgrade this to an 800-MHz system and the price goes up to ~\$2.8 million. If one wants the highest resolution and most sensitive commercially available magnet (950 MHz), the price tag goes up to ~\$8.8 million. These estimates do not include space considerations that also go up disproportionately with field strength. If such funds are not readily available, however, most medium to large size pharmaceutical companies have existing NMR instrumentation and expertise that can be engaged in a drug metabolism structure elucidation strategy with little or no capital investment required.

12.4 NMR EXPERIMENTS

12.4.1 Useful Nuclei

Many nuclei have a nuclear spin and therefore can be monitored using NMR spectroscopy; the ones of primary interest in drug metabolism are ^1H , ^3H , ^{13}C , ^{15}N , ^{31}P , and ^{19}F . Because proton is highly sensitive and hydrogen is present in nearly every drug metabolite of interest, ^1H NMR spectroscopy is by far the most common in drug metabolism studies. The NMR-active isotopes of carbon and nitrogen are useful as well and can occasionally be utilized without enrichment [18], but normally are not directly observable because of their low natural abundance (1.1% and 0.3%, respectively). An advantage of this is that they can be useful “tracer” nuclei that can monitor the metabolic fate of artificially labeled precursors [19,20]. By far, the most valuable use of ^{13}C and ^{15}N is as passive nuclei in proton-observe 2D experiments, which are described later in the chapter. At nearly 100% natural abundance, ^{13}P has been used extensively for studying energy metabolism, nucleic acids, and other naturally occurring phosphates and phosphate esters [21,22], and has potential for studying the fate phosphate-containing drugs and prodrugs [23]. For drugs that contain fluorine, ^{19}F can be used to monitor metabolic fate with little concern for contaminating background signal [23–25]. Tritium is not only a frequently used isotope of hydrogen for mass-balance studies and has properties similar to proton NMR but also has the advantage of having no background signal. However, ^3H NMR is not widely used because it requires special NMR equipment and high levels of radioactive nuclide incorporation [26]. Regardless of the nucleus chosen to observe, there are a plethora of experimental approaches that exploit the various NMR parameters and can be applied to biotransformation studies. These are broken down by their frequency dimensionality and are either one-dimensional (1D) and produce a single frequency (chemical shift) axis or two-dimensional (2D) and produce two frequency axes.

12.4.2 Solvent Suppression

As we saw above, a simple 1D proton NMR spectrum is very rich in structural information, providing chemical shifts, coupling information, and integrals. The primary advantage of 1D NMR is that it is faster than 2D methods and often provides enough structural information to answer the question at hand. One consideration when analyzing drug metabolites is that of solvent suppression. Metabolites of interest from *in vitro* incubations and *in vivo* sources usually contain large amounts of solvents that present very large signals in comparison with the metabolite. These can either be protonated residuals from deuterated solvents or carryover from isolation solvents and can, especially in proton NMR, create a significant dynamic range problem as shown in Fig. 12.4. Furthermore, the solvent signals obscure important metabolite signals in the spectrum. These problems can be partially ameliorated by the application of solvent suppression during the data acquisition. There are a wide variety of solvent suppression pulse sequences that are applicable for NMR-based metabolite ID. These have recently been reviewed [27], and so what follows is a brief description of a few relevant approaches. Application of a selective radio frequency pulse exactly at the solvent frequency (or frequencies) during the interpulse delay is effective for eliminating single or a limited number of solvent peaks, while retaining a uniform excitation across

Figure 12.4 Demonstration of the importance of good water peak suppression for ^1H NMR spectra of aqueous solutions. All spectra were recorded at 500 MHz on a sample of dilute rat urine in 20-mM phosphate buffer, pH 7.4. (a) simple single-pulse ^1H NMR spectrum with the vertical scale expanded 4000-fold higher than the height of the water peak. (b) same experiment as top trace with the addition of a selective 100 mW irradiation of the water resonance for 1 s before data acquisition. This serves to equalize the spin population of the water protons so that they do not contribute to the NMR spectrum, and is referred to as *presaturation*. (c) One-dimensional version of the NOESY experiment with 100 ms mixing time and presaturation of the water peak. The 100-ms delay and phase cycling utilized in the pulse sequence cancels out broad components from the intense water signal arising from inhomogeneous parts of the sample and results in better overall water suppression than presaturation alone. *Source*: Reproduced from Ref. 9 with the permission of Informa Medical and Pharmaceutical Science Books.

the entire spectrum. This is simple to implement in almost any NMR experiment, but will also saturate analyte peaks near or coincident with the solvent signal or peaks in rapid chemical exchange with solvent hydrogens (e.g., NH and OH protons exchanging with H_2O). Solvent suppression approaches that exploit the different relaxation properties of solvent and analyte (e.g., WET) [28] destroy the solvent magnetization using pulsed field gradients, and do not suppress exchangeable proton resonances, but may not provide uniform solvent suppression or excitation in all cases. Various other solvent suppression schemes that create excitation nulls at solvent frequencies have also been widely used, but also result in nonuniform excitation. A particularly useful incarnation of this, called *excitation sculpting*, minimizes nonuniform excitation and produces flat baselines [29]. Solvent suppression approaches that exploit the diffusion differences between solvent and analyte have been reported [30,31] and allow observation of analyte signals which are completely buried under solvent peaks, albeit with a significant loss in sensitivity. Because of the nature of drug metabolism work, it is almost universally true that some sort of solvent suppression will be incorporated into an NMR experimental approach.

12.4.3 Multidimensional NMR

In the study of low level isolated or partially isolated drug metabolites, spectral complexity and signal overlap in 1D NMR spectra can prevent extraction of necessary structural information. One approach for improving spectra dispersion is through the use of 2D methods. The pulse sequences that form the basis of such multidimensional NMR approaches not only enable increased spectral dispersion but also can have the added advantage of giving information on relationships between the various resonances in the spectrum, for example, showing which ones are coupled to each other by scalar or dipolar coupling. These methods have been comprehensively described both in general [32] and in the context of drug metabolite studies [8], so the following is a brief description of the concept and the most important 2D methods for drug metabolism researchers.

The general approach taken for 2D NMR is to apply a series of excitation pulses and incremented delay periods to the sample such that there are two independent variable time intervals in the pulse sequence. One of these is the acquisition time, denoted by t_2 and equivalent to the time domain of a 1D spectrum, and the other is related to the incremented delay and denoted by t_1 . If an NMR FID is acquired for a period t_2 for each of a set of t_1 values, the NMR signal intensity (S) will be a function of both t_1 and t_2 giving a time matrix of data $S(t_1, t_2)$. A Fourier transformation with respect to both t_1 and t_2 produces a frequency matrix, $S(\omega_1, \omega_2)$. This is the 2D spectrum and is simply NMR signal intensity as a function of two frequency axes. The delay t_1 and how and what nuclei are manipulated in the pulse sequence will define exactly what the two frequency axes will represent. The most common class of proton 2D NMR experiment provides information on connectivity between nuclei that are scalar or dipolar coupled to each other. Manifestations of this “correlated” type of 2D experiment include those where the two nuclei are identical (homonuclear) and those where they are different (heteronuclear).

The proton homonuclear experiment, termed *COSY* (*correlation spectroscopy*), is used to show which resonances in a proton spectrum are scalar coupled to each other, that is, generally two or three bonds apart. The resulting spectrum has the conventional 1D NMR spectrum along the diagonal and off-diagonal peaks at chemical shifts corresponding to pairs of coupled nuclei. This is exemplified by the contour plot of the 2D COSY spectrum of 3-nitrotyrosine given in Fig. 12.5, where intensities are represented as contours in the 2D map. A related and very powerful experiment, called *TOCSY* (*total correlation spectroscopy*), provides information on unbroken chains of scalar-coupled protons in one 2D NMR spectrum. Information from these two experiments is often used together as the basic structural elucidation tool. The analogous experiment that exploits dipolar rather than scalar coupling is based on the nuclear Overhauser enhancement spectroscopy (NOESY) (and the closely related rotating-frame Overhauser enhancement spectroscopy, ROESY). The NOESY spectrum looks similar to that of the COSY, except that the off-diagonal peaks are at the chemical shifts of protons which have a mutual NOE and are thus close in space (generally $<5 \text{ \AA}$), but not necessarily close to each other in the molecule.

Although, in principle, heteronuclear 2D NMR can be between any dissimilar pair of NMR-active nuclei, in practice, sensitivity dictates that proton is usually one of the pair and the one that is in the detected (t_2) domain. In drug metabolism, the other (undetected or passive) nucleus is usually ^{13}C or less frequently ^{31}P , ^{19}F , or ^{15}N , and

Figure 12.5 Contour plot of the ^1H - ^1H two-dimensional 500-MHz COSY NMR spectrum of 3-nitrotyrosine. Peaks labeled on the diagonal correspond to the one-dimensional proton NMR spectrum and off-diagonal peaks correlate nuclei that are spin-coupled to each other. *Source:* Reproduced from Ref. 9 with the permission of Informa Medical and Pharmaceutical Science Books.

the experiments are divided into one-bond and multiplebond types. The two principal one-bond experiments are heteronuclear multiple quantum coherence (HMQC) [33] and related heteronuclear single quantum coherence (HSQC). These rely on the strong one-bond coupling between the proton and its attached heavy atom or “heteronucleus,” which in the case of ^{13}C is usually $>100\text{ Hz}$. Analogous pulse sequences typified by the heteronuclear multiple bond correlation (HMBC) exist based on long-range ^1H -X couplings, which can then give connectivity information for heteroatoms that are two to five bonds apart [34]. The ^1H - ^{13}C HMQC spectrum of nitrotyrosine is shown in Fig. 12.6. This presentation, unlike the homonuclear correlation experiments, has no diagonal peak and the axes correspond to the appropriate chemical shift ranges of the ^1H and ^{13}C nuclei, with each peak arising from a C-H pair in the molecule.

12.5 HYPHENATED TECHNIQUES

A technological development that has received a lot of attention in the study of drug metabolism is HPLC directly coupled to an NMR spectrometer. In this hyphenated

Figure 12.6 Contour plot of the ^1H – ^{13}C two-dimensional HMQC NMR spectrum of 3-nitrotyrosine. Each peak identifies a single C–H pair at the intersection of the ^{13}C (vertical axis) and ^1H (horizontal axis) chemical shifts for all CH and CH_2 groups in the molecule. *Source:* Reproduced from Ref. 9 with the permission of Informa Medical and Pharmaceutical Science Books.

LC-NMR approach, an unprocessed or partially processed sample containing the drug metabolite(s) is injected onto a chromatography system, such as an HPLC, and NMR spectra are recorded as the eluant passes through the spectrometer (on-flow mode) or with a chromatographic peak stopped in the flow cell (stopped flow mode). The analytes need not have a chromophore or ionizable group for mass spectrometric detection, because of the nonselective nature of the NMR spectrometer, nor does separation need to be complete, as the inherent frequency resolution of the NMR spectrum makes it possible to analyze many components in a single spectrum. In the case of on-flow mode, the result is a pseudo-2D NMR experiment, where the ω_1 dimension is replaced with the chromatographic retention time. More commonly, however, stopped flow mode is used, where an eluted chromatographic peak is parked with its apex at the center of the flow cell and a series of extended NMR experiments are conducted. As a result, the most highly concentrated part of the chromatographic peak is measured, which should be the purest, given adequate separation from interfering peaks. On the other hand, as the entire peak is normally not in the flow cell, the hyphenated method is usually not as sensitive as isolate-and-concentrate approaches (see below). Another useful hyphenation adds mass spectrometry to create LC-NMR-MS, an adaptation

that allows mass-directed selection of what peaks one might want to acquire NMR spectra on [35] or simply to provide a more complete analytical data set in one experiment [36].

The use of LC-NMR was first reported in 1978 [37] and based on publication records, interest peaked in about 2003, with a much smaller but steady number of reports appearing annually since. Nonetheless, numerous examples of its utility argue for inclusion of this technology in the modern biotransformation tool kit. While proton-observed LC-NMR is normally utilized for sensitivity reasons, ^1H - and ^{19}F -detected LC-NMR has been used to characterize human immunodeficiency virus (HIV)-1 reverse transcriptase inhibitors and glucuronide metabolites [38,39]. LC-NMR has also been used to effectively study unstable metabolites and those recalcitrant to isolation, such as acyl glucuronides [40,41]. A recent review of LC-NMR methods in drug metabolism [5] compares conventional NMR with the hyphenated approach, highlights numerous impactful examples of the latter, and also critically discusses disadvantages and situations where they would be of less utility (mainly based on lower inherent sensitivity). While hyphenated systems will not replace conventional isolation and NMR analysis, they clearly have a niche in drug metabolite characterization. In particular, LC-NMR is most useful when there is a large amount of the desired analyte on column and the analyte is not stable to isolation. Since most flow cells (30–120 μL) will only hold a fraction of a typical HPLC peak, a great deal more material needs to be injected than might be needed if the peak is isolated conventionally. For example, 10 μg on column might only yield 2–3 μg in the active part of the flow cell. The use of ultra high pressure HPLC could more closely match peak volumes to that of the flow cell, but column loading may be limiting with these systems. The biggest advantage of LC-NMR for metabolite ID is when dealing with reactive metabolites or those that are either unstable over time or decompose on drying. In the absence of a stability issue, it is almost always better to isolate more material and reconstitute it in an NMR-friendly solvent to get the most useful NMR data.

Another noteworthy technique inserts an automated solid-phase extraction (SPE) step, between the HPLC and the NMR [42]. The HPLC-SPE-NMR approach incorporates trapping of HPLC peaks containing metabolites onto small SPE columns, which can then be dried and subsequently eluted with high quality deuterated solvents either directly into a flow cell or into NMR tubes for conventional analysis in a fully automated manner [43]. This approach allows for the accumulation of low abundance metabolites on individual SPE cartridges through repeated HPLC injections as demonstrated for human metabolism of phenacetin [44]. This technique avoids many of the unattractive aspects of direct LC-NMR, including the requirement for large amounts of expensive deuterated solvents and limited analyte mass, while allowing the most efficient use of valuable NMR acquisition time.

12.6 EQUIPMENT CONSIDERATIONS FOR DRUG METABOLISM

Although NMR equipment continues to evolve, the cost setting up a laboratory is quite high, as alluded to earlier. As such, it is highly desirable to fully utilize such equipment, especially in today's cost conscious environment. Indeed, in our laboratories, biotransformation scientists normally do their own HPLC and LC-MS studies and collaborate closely with the analytical NMR group when the additional structural information is

required. This is beneficial in that it allows optimum utilization of expensive capital and ensures that domain experts are employed at what they do best. In such cases, it may be that a nominal investment in certain accessories for an existing high field NMR system avoids the cost of setting up a \$2 million laboratory. The following discussion focuses on the ideal equipment for a drug metabolism NMR system and indicates those accessories that are considered required and those that are nice-to-haves.

12.6.1 The NMR Spectrometer

The core component in any NMR spectrometer is the magnet. This component will typically last upward of 20 years and will survive many cycles of upgrades to other parts of the system. This, combined with the sensitivity and resolution advantages of higher fields mentioned above, dictates the use of the strongest magnet that the budget will allow and ideally no less than 600 MHz. Nearly all systems that can be purchased today are only available with self-shielded magnets which greatly minimize space requirements and reduce the distance from which accessories (e.g., chromatography systems) can be located. The footprint of such a system is dramatically smaller than with a conventional magnet, which will reduce facility costs. The spectrometer should be equipped with a minimum of two excitation channels—one for proton and one for heteronuclei (broadband), both of which should have the capability of producing shaped pulses. Optionally, a system that can observe ^{19}F simultaneously with proton can be used to monitor metabolism of fluorine-containing drugs. The spectrometer should also have a Z-axis gradient amplifier capable of producing a gradient across the sample of at least 30 G/cm (and preferably 60 G/cm) with rapid recovery time (<1 ms), enabling newer solvent suppression techniques and diffusion editing experiments to be employed. Finally, the system should have a sample temperature control unit capable of maintaining a uniform temperature across the sample of $\pm 0.1^\circ\text{C}$ or less.

12.6.2 The Probe

For most drug metabolism studies, the actual amount of sample is limited, and in such cases the smallest volume probe is usually the best [45]. Ideally, the small sample probe would be cryogenically cooled; however, this can be a significant cost factor. For example, at the time of this writing, adding a small volume cryogenic probe to a system already equipped with one will cost about \$100,000, whereas purchasing a complete cryoprobe accessory and all of the associated hardware costs between \$250,000 and \$350,000. Currently, the smallest commercially available tube-type NMR probes are 1.0 and 1.7 mm for room temperature and cryogenically cooled probes, respectively with the latter being three- to fourfold more sensitive. All things considered, if budget is limited and access cannot be had to an NMR system with an existing cryogenic platform, the best bet would be the 1.0 mm room temperature probe. If costs were no object or if an NMR system with the cryogenic platform was being accessorized, the slightly larger (1.7 mm) cryogenically cooled probe would be the best choice and the current optimum for sensitivity. For hyphenated systems, the ideal probe is a small volume flow cell, matched as closely as possible to the typical peak volume of the attached chromatographic system. Commercially available probes that are cryogenically cooled and can operate in flow or tube mode are currently available in 30–120 μL active volumes (flow mode), corresponding to 3–5-mm tube diameters. Regardless of

the choice of probe, it should have a Z-axis gradient capability and be capable of observing proton and exciting ^{13}C , ^{15}N , ^{31}P , etc.), again with simultaneous ^1H and ^{19}F capabilities nice-to-have.

12.7 SAMPLE PREPARATION

It was recognized as early as the 1960s that the resolving power of NMR dramatically lowers the purity requirements for getting useful information [46]. Indeed, early examples of NMR-based drug metabolism studies conducted directly on unprocessed urine from animals dosed with ampicillin [47] and humans with acetaminophen [48] demonstrate the power of NMR to measure drug-related compounds in complex media. Benefiting from very high tissue concentration and no competing background signal, metabolites of 5-fluorouracil have even been measured in live animals using ^{19}F magnetic resonance spectroscopy (MRS) [49]. Applications of this approach for other anticancer drugs using ^{13}C enrichment have been reported (see the review in Ref. 50 and references therein). Such cases will be the exception, however, and will work only when high levels of metabolites are present in the biofluid or tissue, or in cases confirming known metabolites. Microbial metabolism has been used to scale-up metabolites observed in higher species to provide sufficient materials for NMR studies [51]. More typically, application of NMR to drug metabolite identification involves extraction of the metabolites from the tissue, fluid, or incubation medium of interest, purification by some sort of chromatography, liquid–liquid or SPE, then redissolving the dried down isolate in an NMR-suitable solvent thus achieving higher sample concentration and reduced solvent interference. The concentrated sample is placed into an NMR tube and data are collected and interpreted.

Because of the nonselectivity of NMR, sample preparation is the single most important step for the success of NMR-based drug metabolite structure identification. Any left-over trace of the original matrix, be it protein, buffers, or residual solvents can introduce NMR signals that are orders of magnitude greater than the metabolite signals. It is frequently the case that such interferences are NMR specific and not obvious in an HPLC chromatogram or an MS analysis. We have recently introduced methodology that shows advantages in improved sample quality, reduced sample preparation time, and the results in lower sample requirements [52]. This robust methodology was established for rapid structure determination of microgram quantity drug metabolites by using high field NMR equipped with a cryoprobe. In this new approach, drug candidate metabolite formation occurs in a single 10–30 μM , 2–5 mL incubation of microsomes, hepatocytes, or recombinant drug-metabolizing enzymes (typically cytochrome P450s and UDP-glucuronosyl-transferases). Following precipitation of proteins and solvent removal, the reconstituted metabolite-enriched solution is repeatedly injected onto an HPLC/MS system and fractionated. Fractions are collected into a 96-well plate and dried. On the basis of the MS profile, selected fractions are then reconstituted in just enough deuterated solvent to fill the NMR tube, typically 30 μL for a 1.7-mm tube. NMR spectra of these isolated metabolites are then acquired on a 500 or 600 MHz spectrometer equipped with a cryogenic probe. The methodology has been successfully employed as an extension of HPLC/MS/MS-based metabolite identification. When metabolites are present in 0.5–10 μg quantities, 1D ^1H -NMR and homonuclear 2D NMR experiments with satisfactory S/N can be routinely obtained.

12.8 DISCOVERY APPLICATIONS

It is no surprise to individuals currently engaged in the field of pharmaceutical research that performance expectations are increasing along with shrinking timelines. Discovery programs have aggressive and hard deadlines and hence information delivered too late is of little use. This is no less true for drug metabolism studies in early phase programs, where minimizing metabolic liabilities is an intricate part of selecting the right candidate to move forward. This has fostered a heavy reliance on modern LC-MS-based approaches that can quickly analyze metabolites from an *in vitro* incubation and frequently provide enough information to advance the program. Sometimes, however, crucial information, such as exactly which atom in a particular part of the molecule is modified cannot be answered even with advanced MS techniques. Fortunately, the rich information content of a simple 1D ^1H NMR spectrum can often provide sufficient information to remove that ambiguity. There are various examples in the literature where simple one-dimensional ^1H NMR was sufficient to provide the ancillary information needed to yield an unambiguous structure for metabolites under study and thus have programmatic impact [8,53]. This type of “good enough, proceed onward” approach is appropriate when rapid decision making takes precedent over absolute accuracy.

A recent example of the power of the new rapid throughput NMR method described in the previous section is the rigorous analysis of oxidative metabolites and glutathione (GSH) conjugates of the antidepressant and anxiolytic drug, trazodone. In this study, 8 metabolites were quickly characterized from samples generated in single 2 mL incubation of NADPH- and GSH-supplemented human liver microsomes at 30 μM drug substrate concentration [52]. Incubation conditions, post-incubation workup, and sample preparation by HPLC closely resembled a typical biotransformation experiment. The accurate mass, MS/MS, and NMR spectral data characteristics of seven of these metabolites are summarized in Table 12.1, and the aromatic region of the ^1H -NMR spectra for each are shown in Fig. 12.7. Combined analysis of these results allowed elaboration of the metabolic fate of trazodone under these conditions as depicted in Fig. 12.8. Among the metabolites detected, the structure and regiochemistry of four metabolites, Met1a, Met3, Met4, and Met5, were unambiguously characterized using ^1H -NMR, ^1H -COSY, and ROESY techniques on total amounts of individual metabolites ranging from 1 to 10 μg . Regiochemistry assignments for the other three metabolites (Met2, Met6, and Met7) were proposed on the basis of the observed chemical shifts and similarities to other metabolites. A minor metabolite, Met1b, was not structurally defined beyond the gross structure assigned from MS/MS data primarily because of insufficient quantity. It is important to point out that the execution time for this entire workflow was a few consecutive days, during which time sample stability was closely monitored.

In addition to trazodone, a large number of unpublished examples from our laboratories have proven the value that this rapid microgram-level NMR method adds by avoiding time-consuming preparative-scale metabolite generation and purification and circumventing the technical complications associated with online LC-NMR. The turnaround time of metabolite structure determination using the approach described here synchronizes NMR-based structural elucidation with the typical compound optimization cycle times, during which medicinal chemists modify the identified metabolic soft spots while performing other iterative lead optimization activities. Thus, timely

and rigorous structural characterization of drug metabolites can still have a maximal impact on the drug discovery process.

12.9 DEVELOPMENT APPLICATIONS

The characterization of a drug's metabolites continues to play a critical role in the development process. As a drug proceeds from discovery into development, the emphasis shifts from speed to completeness and absolute accuracy takes precedent over expediency. As such, considerably more time and resources are applied to exhaustively characterize the metabolic products of a drug and greater efforts are put into isolating sufficient quantities of important metabolites for full structural characterization. Major drug metabolism-related tasks in development involve metabolite profiling, determination of metabolite exposures, and assessment of metabolic clearance pathways in humans and toxicological species [54,55] for gaining an understanding of the metabolites' contributions to on-target pharmacology and off-target receptor-mediated toxicology. As such, metabolite identification studies remain an integral part of these preclinical and clinical drug development activities. The recently issued guidance on Safety Testing of Drug Metabolites, also commonly referred to as *Metabolite in Safety Testing (MIST)* provides a framework for completion of the metabolite characterization goal [56,57]. The guidance provides recommendations on when and how to identify, characterize, and evaluate the safety of unique human metabolites and major circulating metabolites that are present in disproportionate levels in humans as compared to preclinical species used in toxicology studies. The industry and regulatory focus on these activities underscores the importance of detecting and characterizing drug metabolites despite the often complex metabolic profiles, multiple enzymatic pathways, and generation of numerous metabolites of varying concentrations from the parent drug compounds.

Frequently, metabolite characterization at the drug development stage will involve the application of two-dimensional NMR experiments that provide the needed information for unambiguous structure determination [58]. A recent example illustrates the unambiguous structural elucidation of major metabolites from medroxyprogesterone acetate using 2D NMR [59]. According to the authors, this work circumvented the need to chemically synthesize authentic compounds to confirm the metabolism. The sensitivity of modern NMR equipment makes routine acquisition of 2D NMR on low microgram quantities possible, allowing NMR to become a mainstream analytical tool for metabolite ID in drug development. This is exemplified in recent work from our laboratory, where two major circulating metabolites in dog (M21 and M22) of BMS-275183, a taxane analog being evaluated for its potential anticancer properties, were characterized from samples containing $\sim 74 \mu\text{M}$ ($\sim 10 \mu\text{g}$) of each metabolite [60]. Proton NMR spectra, acquired on a 700 MHz cryoprobe system, revealed impurities in the sample that prevented definitive structure characterization from the ^1H spectrum alone. Various 2D-NMR experiments, including homonuclear COSY and heteronuclear ^1H - ^{13}C HSQC and HMBC data provided complete proton and carbon chemical shift assignments of M22, and all but four-carbon assignments of M21. Together with key HMBC H-C correlations (Fig. 12.9), these provided definitive metabolite structure information. These experiments took a total of about 72 h to complete with a cryoprobe, without which this analysis would have been time-prohibitive. Prakash *et al.*

Figure 12.9 Region of the ^1H – ^{13}C HMBC 2D NMR spectrum of a 74 μM sample of M22 of BMS-275183 at 700 MHz. Crosspeaks are labeled with atom numbering indicating the H–C correlations that they correspond to in the structure.

[61] have recently used LC-NMR, 1D, and heteronuclear 2D NMR to provide critical structural information for the definitive identification of a novel quinoline metabolite (M4) and a sulfite conjugate (M28) of Torcetrapib and two unusual metabolites resulting from C-demethylation of CP-533,536 [62]. Multidimensional NMR was critical in differentiating N- and O-glucuronidation of Maxipost and elaborating the mechanism of N-glucuronidation in support of clinical trials [63].

The unique molecular/spectroscopic fingerprints provided by NMR allow discrimination of complex mixtures of geometric and regioisomers, decomposition products, and of impurities unrelated to the drug product, all within a single sample. This, in turn, places NMR in a unique and favorable position to be useful even in the case where high purity and isolation cannot be achieved chromatographically or isolated samples decompose over time. As previously noted, characterization of multiple metabolites in a single sample is feasible. While isolation of individual metabolites is usually the goal in development studies, the resolving power of NMR has been applied to the characterization of mixtures of coeluting metabolites. Analysis of chromatographic isolates of human urine by NMR spectroscopy was used to demonstrate that in human, 1-hydroxytacrine coeluted with 3-hydroxytacrine. In preclinical metabolism studies with tacrine, the 3-hydroxy metabolite was not observed and thus NMR provided the first clues to a novel human metabolite [64]. More recently, coeluting regioisomeric glucuronides of BMS-690514 [65] have been identified. A peak containing the M8 metabolite of BMS-690514 was isolated from rat bile after administration of [^{14}C]BMS-690514. Positive mode electrospray ionization (ESI) LC-MS/MS analysis indicated that M8 had an m/z at 561 (192 Da higher than BMS-690514), suggesting it was a glucuronide

Figure 12.10 The frequency resolving power of NMR permits structure ID on two components in a mixture. The radiochromatogram of purified M8 of BMS-960514 (top right) shows the presence of a single peak and proton spectra with assignments of this isolated M8 peak (bottom), showing that it consists of a mixture of M8a and M8b metabolites.

conjugate of monohydroxylated BMS-690514. NMR analysis revealed that the isolated M8 peak contained a major (M8a) and a minor (M8b) metabolite at a 3:1 ratio. Both metabolites were successfully characterized within the mixture using 1D and 2D NMR methods. For M8a, glucuronidation occurred at the hydroxyl in position 23. For M8b, glucuronidation occurred at the hydroxyl group on position 25' (Fig. 12.10). In both these examples, mass spectrometric evaluation was not sufficient to reveal the presence of multiple metabolites in single chromatographic peaks.

Isotope labeling techniques have assisted in the study of drug metabolism, distribution, excretion, and the identification of metabolites from drugs of interest [19]. A number of these labels can be measured directly or indirectly by NMR. For example, the replacement of a proton within a drug molecule by deuterium (^2H) or tritium (^3H) can be assessed by acquiring a ^1H spectrum and observing a loss of signal of the resonance containing the label. Similarly, a deuterium or tritium NMR spectrum of the sample can be acquired in cases where one of those hydrogen isotopes is incorporated into the molecule. This presents unique opportunities for quantitating how much of the label has been incorporated, as well as following the metabolic fate of the label. Simultaneously, this makes NMR a powerful quality control and mechanistic tool in isotope-assisted metabolism studies. The formation of a metabolite from BMS-690514, an oral oncologic agent, is a great example of the utility of isotope labeling and NMR. BMS-690514 contains a pyrrolotriazine group subject to oxidation at carbon 16, Fig. 12.11, resulting in the formation of metabolite M1, a primary hydroxylated

Figure 12.11 ^1H NMR spectrum of M1 (bottom), deuterated M1 at position 16 (middle), and deuterated parent at position 16 (top). The reduced intensity of the 16 proton in parent and metabolite indicates the amount of deuterium incorporation and the fact that this level is preserved during biotransformation.

metabolite identified *in vivo*. NMR data indicated that M1 underwent a structural rearrangement. To gain insight into this rearrangement $[16\text{-}^2\text{H}]\text{BMS-690514}$ was prepared and shown to contain the deuterium on the expected position 16 (Fig. 12.11). Integration of H16 in the ^1H NMR spectrum of $[16\text{-}^2\text{H}]\text{BMS-690514}$ revealed that approximately 40% was protonated, and therefore the percent of deuterium label incorporation at this position was $\sim 60\%$. Subsequently, M1 generated from human liver microsomes (HLMs) incubations with $[16\text{-}^2\text{H}]\text{BMS-690514}$ was characterized by NMR. Integration of H16 in the ^1H NMR spectrum of $[\text{2H}]\text{M1}$ indicated that the deuterium label was quantitatively preserved at position 16 (Fig. 12.11), significantly limiting the number of possible mechanisms for the formation of this metabolite [73].

Finally, the quantitative aspects of NMR described above make it a potentially valuable tool for use in compliance with MIST guidance. In this capacity, quantitative NMR measurements of biologically generated drug metabolites can subsequently be used as reference standards for quantitative work using LC/MS [6]. In this approach, ^1H NMR is applied as the method of choice, as it is both a qualitative and a quantitative tool, allowing structure determination, purity check, and quantitative measurement of the isolated metabolites. Another approach is to assimilate data from NMR spectroscopy and liquid chromatography-ultraviolet-mass spectrometry (LC-UV-MS) with plasma pooling methods to generate reliable area under the curve (AUC) values for metabolites present in the plasma of preclinical species, followed by the translation of this information to quickly assess their relationship to human-produced metabolites as dictated by the MIST guidance [66].

12.10 STEREOCHEMICAL CONSIDERATIONS

In the quest for novelty and optimum potency, chirality is frequently engineered into drug molecules. Metabolism can confound this already complex situation by introducing additional stereochemical modification. In these cases, absolute stereochemistry determinations become an essential part of characterizing the metabolite. Of course, X-ray crystallography and vibrational circular dichroism (VCD) have been used to solve such problems [67,68], but are not routinely useful for metabolites because they require many milligrams of material. NMR cannot directly distinguish enantiomeric compounds, but NMR-based methods for the determination of absolute stereochemistry have been developed, which rely on interactions between the molecule under study and various chiral reagents to form *in situ* diastereomers that *can* be differentiated (for reviews, see Refs 69 and 70). This can be achieved through covalent chemical derivatization, for example, formation of Mosher esters [71] or through transient interactions with chiral solvents or solutes [70]. The success of these methods lies in the ability to correctly predict chemical shift or coupling constant differences that arise from these interactions or chemical modifications. A covalent derivatization approach using nonchiral reagents was recently used to assign the stereochemistry of a major circulating hydroxylated metabolite of a corticotropin releasing-factor receptor antagonist [72]. The metabolite's stereochemistry was revealed by extrapolating the NOE-derived conformation of its cyclic oxazolidine derivative back to the underivatized metabolite. While not a panacea for absolute stereochemical determination, with the limited number of tools available, the NMR approaches described above can be brought to bear on important stereochemical problems that crop up in drug metabolism.

12.11 CONCLUSIONS

NMR spectroscopy has been and will continue to be a significant part of the drug metabolite structure elucidation toolbox. The type of information it provides exquisitely complements that obtained from the mainline analytical tool used for drug metabolism structure work, LC-MS. Frequently, it makes the difference between drawing a box around a large part of the molecule to indicate a region of metabolism and identifying the exact atom which is modified, and this information is more often than not crucial for guiding chemistry efforts to mitigate metabolically labile "soft spots" in a molecule. The qualitative and quantitative information obtainable from NMR provides a unique advantage when attempting to unravel extensive and complex metabolism. By optimizing isolation, sample preparation, and NMR parameters, it is possible to generate useful NMR data coincident with need to meet the demands of drug discovery and development. Additionally, NMR can deliver information on absolute metabolite levels and the fate of incorporated stable isotopes and reveal new metabolites through mixture analysis, which is difficult or impossible to accomplish with any other technique. Constantly pushing against sensitivity limitations, technology developments have led to the current state of NMR's ability to obtain interpretable 1D ^1H -NMR spectra of drug metabolites in a time and cost-effective manner with submicrogram quantities of material. When 2D NMR experiments are needed, sample requirements increase to $\sim 5\text{--}10\mu\text{g}$ depending on the complexity of the structure (e.g., conjugates) and NMR properties of the sample. Continued enhancements to sensitivity through

foreseeable future developments in probe technology and perhaps less tractable access to higher magnetic fields will further lower the sample requirements and make NMR spectroscopy even more useful.

13.1 SUMMARY

Tissue distribution studies, which are part of a suite of experiments known as *absorption, distribution, metabolism, and excretion (ADME)* studies, are performed to understand the disposition of xenobiotics and biotherapeutic drugs after administration to animals and humans. This chapter describes the following three approaches used to study the tissue distribution of chemical and biological compounds in laboratory animals: (i) organ collection, homogenization/combustion, and liquid scintillation counting (LSC) analysis; (ii) whole-body autoradiography (WBA), which includes quantitative whole-body autoradiography (QWBA); and (iii) microautoradiography (MARG), which qualitatively resolves the localization of compounds to the cellular level in a histological preparation. LSC, WBA, QWBA, and MARG studies require the use of a radiolabeled chemical or biological test compound, which provides for the tracking and quantification of both the parent molecule and potential metabolites that might be formed. A radiolabeled test drug is administered to laboratory animals, which are later euthanized at different time points. Samples of the animal's entire body, organs, tissues, and excreta are then analyzed to determine the concentrations of the test-drug-derived radioactivity in the various biological matrices. Tissue concentration versus time profiles can then be constructed to provide data for organ- or tissue-specific pharmacokinetic (PK) compartmental analysis. The animal tissue distribution data are then

used to help evaluate pharmacology and toxicology findings and to predict human exposure to drugs and metabolites.

Dissection and LSC techniques were the prevalent methods for evaluating drug distribution up until about 1995, when QWBA began to be used. This technique entails the removal of organs followed by further processing and analysis of solubilized organ homogenates and/or the combustion of the organ and/or homogenates. The resulting drug-derived radioactivity is then quantified using LSC to determine the radioactivity concentration in the organ.

QWBA is an imaging technique that provides both spatial and quantitative radioactivity concentrations in tissues of intact laboratory animals. The main advantages are minimal sample processing/alteration and provision of true tissue concentrations. This technique begins when each animal is euthanized at their respective time point post dose, and the carcass is quickly frozen. The frozen carcass is then embedded in a frozen block of supporting media and cryosectioned to obtain representative *in situ* samples of all organs, tissues, biological fluids, ingesta, and excreta. Whole-body sections are then dehydrated, exposed to phosphor imaging plates along with radioactive image calibration standards, and the resulting digital images are analyzed to determine tissue concentrations and to show detailed spatial distribution patterns. Sven Ullberg pioneered the WBA technique in 1954, and the technique was made quantifiable by Luckey in 1975 when he developed phosphor imaging technology or radioluminography. QWBA limitations include (i) tissue concentrations determined by QWBA (or LSC) can include parent drug, plus its metabolites, and/or degradation products and (ii) it is difficult to evaluate short-lived isotopes.

MARG provides pharmaceutical scientists with a high resolution tool to investigate spatial localization of radiolabeled drugs at a tissue and cellular levels. The basic procedure requires dosing of animals with a radiolabeled substance, followed by the removal and freezing of organs/tissues, cryosectioning and section mounting, and exposure to nuclear photographic emulsion. The tissue sections are then developed, stained, and evaluated microscopically to evaluate distribution at the cellular level. There are several examples in the literature of investigators attempting to obtain quantitative data from MARG preparations; however, MARG is prone to many artifacts and calibration standards are not applied, which makes true quantitation problematic. This chapter discusses the history, advantages, limitations, and examples of the application of each technique.

13.2 INTRODUCTION TO TISSUE DISTRIBUTION ASSAYS

Tissue distribution studies, which are part of a suite of experiments known as *absorption, distribution, metabolism, and excretion (ADME)* studies, are performed to understand the disposition of xenobiotics and biological drugs after administration to animals and humans. The goal of these studies is to determine how the body absorbs drugs and then how the drug is distributed throughout the body, metabolized, and then eliminated from the body. Regulatory agencies around the world require that this information be determined for the registration of new drugs. This chapter focuses on three approaches used to study the tissue distribution of chemical and biological compounds (small and large molecular weight entities) in laboratory animals and how they are used in preclinical drug research. The three approaches discussed are (i) organ collection,

homogenization/combustion, and LSC analysis, which is commonly referred to as the *cut and count* procedure; (ii) WBA, which includes QWBA; and (iii) MARG, which qualitatively resolves the localization of compounds to the cellular level in histological preparations.

LSC, WBA, QWBA, and MARG studies require the use of a radiolabeled chemical or biological test compound. Small molecular entities (chemical compounds that have molecular weights of <600) Dalton and large molecules (e.g., peptides, proteins, enzymes, oligonucleotides) need to be radiolabeled with an appropriate isotope [most often carbon-14 (^{14}C), hydrogen-3 or tritium (^3H), sulfur-35 (^{35}S), or iodine-125 (^{125}I)] so that the compound can be accurately imaged/identified, localized, and quantified in various tissues, fluids, and excreta. The radiolabeled test drug is synthesized in a radiochemistry laboratory, and the position of the radiolabel on/in the molecule is usually known for small molecules (but may not be for large molecules). The radiolabel provides a method for tracking both the parent molecule and metabolites that retain the labeled portion of the molecule. The radiolabel also enables the specific identification and quantification of metabolites that contain the radiolabel, using radio-high performance liquid chromatography (HPLC) techniques and mass spectroscopy.

In general, small organic molecules are labeled with ^{14}C , ^{35}S , or ^3H [1], and larger molecules, such as proteins and peptides, are commonly labeled using ^{125}I (and sometimes ^{35}S). ^3H is often used in drug discovery because it can usually be done relatively quickly, and it is easier to label compounds with ^3H than with ^{14}C . However, it is important to verify the stability of the ^3H label since ^3H -labeled xenobiotics are known to sometimes undergo hydrogen exchange with water [2]. The extent of *in vivo* stability can be monitored by determining the concentration of radioactivity in fresh (wet) and evaporated samples of plasma and/or urine obtained from the animals to be used for the study. The radioactive counts obtained from the wet and dried samples may be compared to see if there is a difference. A similar situation exists for large molecule peptide and protein drugs that are radiolabeled with ^{125}I . In this case, the protein-bound ^{125}I often becomes dissociated from the test article *in vivo*, and this must be characterized to interpret tissue concentration data. This is discussed further in Section 14.4.2.10.

The study designs for examining tissue distribution are varied, but a few basic designs are currently being used in the pharmaceutical industry. In the most basic design, a radiolabeled test drug is administered via a relevant dose route [e.g., orally, intravenously (IV), topically, inhalation, ocular] to laboratory animals. At various time points after dosing, subjects are euthanized, and samples of the animal's organs, tissues, and excreta are then analyzed to determine the concentrations of the test-drug-derived radioactivity [e.g., organs, tissues, plasma, bile, intestinal contents, urine, feces, cerebrospinal fluid (CSF)]. Tissue concentration versus time profiles can then be constructed to provide data for tissue-specific PK compartmental analysis.

Drug tissue distribution studies are routinely conducted in rodents, rabbits, canines, and nonhuman primates. The choice of the animal test model depends on the purpose of the study. In most cases, the animal model will mimic the expected PK in humans, but it may answer specific questions (e.g., toxicology, pharmacology, oncology, genetic modifications). The number of time points used and the overall duration of the study are also important variables to be considered. Time points should be designed to obtain useful and reliable tissue concentration–time profile data. The following tissue PK parameters can then be determined: maximal drug concentration reached (C_{max}); time

of maximal concentration ($T_{\max}$); area under the time–concentration curve (AUC), which describes tissue exposure to a drug; and terminal elimination half-life ($T_{1/2}$), which describes how long it takes for a tissue to eliminate a drug. The choice of time points to be used for the study will determine how reliable the PK data will be, and it requires at least 6, but 10 usually provide enough to enable the determination of reliable PK parameters for many tissues. To obtain reliable tissue PK parameters, there must be enough time points to capture the $T_{\max}$ and establish a reliable $T_{1/2}$. Statistically speaking, the portion of the time–concentration curve used to determine the $T_{1/2}$ for each tissue must have an r^2 value of 0.8 or higher [3], and there should be at least 3 or more time points in that part of the curve. If reliable animal tissue PK parameters are not obtained using enough time points then predictions of human tissue PK exposure must be treated with caution.

Tissue distribution study designs have changed over the years in response to new technology and ethical animal treatment concerns. Most notable has been the change from using three animals per time point and six to eight time points to using one animal per time point and more time points. Before the implementation of QWBA, when organ homogenization and LSC was used to examine tissue distribution, studies were designed to use three animals per time point and six to eight time points because of high variability observed in the organ concentrations. This variability was presumably due to inconsistent effects of organ exsanguination, cross-contamination of organs by body fluids, and inconsistencies associated with organ collection, homogenization, and further sample processing (sample combustion and/or solubilization and LSC detection efficiency). However, as QWBA techniques began replacing the LSC method, many investigators found relatively lower variability in tissue concentrations among animals at the same time point [4]. This was believed to be due to analysis of intact animal carcasses that were snap frozen on termination, thus preserving a “near-*in vivo*” snapshot of drug distribution over time. This also eliminated the variable effects of exsanguination, organ homogenization/processing, and/or the possibility of organ cross-contamination during organ removal and sample handling. Early investigators who developed QWBA techniques also recognized that the use of more time points resulted in more reliable tissue PK parameters [5]. In this way, QWBA has provided the ability to produce the highest quality, and true, “tissue” concentration data (as opposed to organ homogenate data), as well as the most conservative and ethical use of laboratory animals. Nevertheless, organ dissection/homogenization and LSC are still used today by some pharmaceutical companies that have not yet realized the benefits of and/or accepted QWBA as the method for conducting drug distribution studies. To those ends, this chapter describes the techniques of “cut and count” LSC organ analysis and autoradiography (ARG) tissue analysis and how they are used in drug discovery and development.

13.3 ORGAN DISSECTION, HOMOGENIZATION, AND LIQUID SCINTILLATION ASSAYS

Until the early 1990s, organ dissection, homogenization, and LSC techniques were the prevalent methods for evaluating drug distribution. The technique [6] begins with the process of euthanasia. Typically, animals are deeply anesthetized, and blood is

removed via cardiac puncture, followed immediately by the dissection of the animal, where organs of interest are removed, trimmed, rinsed, weighed, and samples are obtained for homogenization, solubilization, and/or oxidation. Investigators should be aware that exsanguination effects many physiological processes [7] that can alter drug distribution, and so tissue concentration data obtained from tissues removed from a carcass need to keep that in mind when interpreting data obtained in this manner. Technicians performing the necropsy are normally required to wash their instruments between individual organ collection to reduce the possibility of cross-contamination of organs during removal. Technicians must assure that all connective tissue, fat, and other fluids are consistently removed from each organ. The number of organs removed can vary considerably, but normally, ~25–30 organs are removed, which include adipose (abdominal and brown) tissue, adrenal gland, blood, bone, bone marrow, brain, cecum (and contents), epididymis, esophagus, eyeball, Harderian gland, kidney, large intestine (and contents), liver, lung, lymph nodes, myocardium, ovary, pancreas, pituitary gland, prostate, salivary gland, seminal vesicles, skeletal muscle, skin (nonpigmented and pigmented), small intestine (and contents), spinal cord, spleen, stomach (and contents), testis, thymus, thyroid, urinary bladder (and contents), and uterus. Organs are then prepared for homogenization and/or combustion (or oxidation). Organs with a heterogeneous tissue composition, such as bone/bone marrow, pituitary gland, spleen, liver, kidney, brain, and muscle, are usually homogenized using a probe homogenizer and/or manual mincing/crushing before sample aliquots are obtained for drying and combustion. Small organs (usually weighing <1 g) such as adrenal glands, pituitary gland, and small samples of tissues for combustion may be placed directly on combustion cones. All samples are allowed to dry to improve complete and uniform combustion. Often triplicate aliquots (0.100 g) of the homogenized sample or an entire organ will be analyzed to monitor/control variability. Each sample aliquot for analysis must be weighed before combustion in the sample oxidizer to the determination of the concentration of drug-derived radioactivity in the sample. Each sample is individually placed into a combustion instrument and then burned completely. The liberated $^{14}\text{CO}_2$ or ^3H gas is then trapped in a solution, and the radioactivity is determined by LSC. Blank samples that contain a known amount of radioactivity are often oxidized and compared to noncombusted standards to determine the percentage of recovery and efficiency of the combustion process, although it must be realized that each tissue may have different oxidation efficiencies and this is not usually determined due to the significant amount of extra work involved. Nevertheless, the efficiency of sample oxidizers must be verified before and during sample oxidation because the performance of these instruments can vary as samples are being processed. Furthermore, the potential exists for carry-over of radioactivity from one sample to another, which, of course, could alter the concentration data. Most sample oxidizers require loading and unloading and careful monitoring by a technician.

An alternative to sample combustion is sample solubilization, where organ homogenates and/or entire small organs are solubilized using a strong caustic reagent. Aliquots of the solubilized sample are then bleached to remove any color that can impede the efficiency of the LSC instrument, and this is typically done by adding peroxide to the sample before scintillation fluid is added and the samples are counted by LSC.

LSC of the resulting samples relies on the performance of the scintillation analyzer. The LSC analyzer detects photons of light that are produced as the radioactive β

particles emitted from decaying isotopes, such as ^{14}C or ^3H , excite the scintillant. The photons emitted are detected by photomultipliers and the signal is translated into a “count” of the radioactivity. The radioactivity [i.e., counts per minute (cpm)] in each sample is then converted to disintegrations of radioactivity per minute (dpm) by means of an external standardization and a quench curve that are part of LSC analyzer protocols. Quenched standards are typically used to calibrate the liquid scintillation counter on each day of analysis, and samples are typically counted for at least 5–10 min each.

The LSC data (dpm) is then used to determine the concentration of drug-derived radioactivity in the sample by dividing the decay per minute by the weight of the sample, which if diluted during homogenization, must be corrected using a dilution factor. It is important for researchers to recognize that the concentration data obtained this way is from organ homogenates and is not true tissue concentration. All organs are composed of several different tissue types, and each tissue of an organ can have vastly different concentrations of the test drug. The ability to determine organ concentration enables researchers to determine the percentage of the radioactive dose that has been taken up in an organ because the total organ weight was obtained at necropsy. This percentage of radioactive dose per organ per time point is usually determined and reported.

In conclusion, exsanguination, organ dissection, homogenization, oxidation or solubilization, and LSC techniques offer pharmaceutical researchers a method to determine organ concentrations; however, true tissue level concentration determinations cannot be obtained. Nevertheless, LSC techniques have been a valuable tool to study the ADME properties of drugs, and it will undoubtedly be used in the future as an alternative method to WBA.

13.4 WHOLE-BODY AUTORADIOGRAPHY

Today, most tissue distribution studies used to support new drug registrations are performed using QWBA techniques [8], which is the imaging and quantitation of drug-derived radioactivity concentrations in tissues of preclinical species. QWBA has numerous advantages over “cut and count” LSC analyses. The key advantages are tissue, rather than organ, concentrations are obtained; there is no cross-contamination from tissues; and the variability due to exsanguination is eliminated. As previously mentioned, QWBA typically uses one animal per time point, and each animal is euthanized and then the carcass is rapidly snap frozen typically in a dry ice/hexane bath (Fig. 13.1a). This process eliminates redistribution of compounds post death. A small blood sample is normally obtained before freezing and can be collected via cardiac puncture or alternative methods. Plasma may then be prepared from a portion of the blood sample. The frozen carcass is then embedded in a frozen block of supporting media (Fig. 13.1b) and precision cryosectioned (Fig. 13.1c) in a sagittal orientation at 40 μm thickness using a special macrotome to obtain representative *in situ* samples of all organs, tissues, biological fluids, ingesta, and excreta. Approximately 5–10 whole-body sections at various depths through the animal are necessary to collect the typical set of 40–50 tissues analyzed by this method. These samples, collected on adhesive tape, are then dehydrated (approximately two days in a cryomacrotome or more rapidly using a lyophilizer). Phosphor imaging has replaced traditional film ARG

Figure 13.1 Whole-body autoradiography methods. (a) The carcass is frozen in a hexane-dry ice bath, (b) whole-body sections are dehydrated, (c) sections are exposed to phosphor imaging plates along with radioactive image calibration standards, (d) the imaging plates are scanned by a phosphor imaging plate scanner, and (e) grayscale digital images of the radioactivity in the sections are obtained for image analysis to determine tissue concentrations. (See color insert.)

because of its larger linear range and shorter exposure times. Samples are opposed to phosphor imaging plates along with radioactive calibration standards (Fig. 13.1d). After an appropriate exposure period (1–14 days, depending on the isotope and/or amount of radioactivity present in the sample), the imaging plates are scanned by a phosphor imaging plate scanner, and grayscale digital images of the radioactivity in the sections are obtained (Fig. 13.1e). The digital images are then calibrated using image analysis software so that different grayscale levels, which are assigned by the image analysis software, are interpolated to provide a quantitative value of radioactivity in all tissues imaged. Data can be reported as nanocuries (nCi) or microcuries (μCi) of radioactivity per gram of the tissue or in terms of drug equivalents per gram of tissue (or matrix). Digital QWBA images typically have pixel resolutions of $100\mu\text{m}^2$; therefore, accurate measurements can be obtained even for small tissues; however, today's phosphor and direct nuclear imagers often offer pixel resolutions down to 10 and/or $25\mu\text{m}^2$, which are among the highest resolving powers available.

13.4.1 History, Strengths, and Limitations of Whole-Body Autoradiography

The eloquent method of QWBA came from crude beginnings in the 1800s. In 1867, Niepse de Saint Victor first described the phenomenon of ARG as the “persistent activity due to an unknown chemical radiation” [9,10]. This observation lead another scientist named London to perform an experiment in which an autoradiographic image of a frog treated with radium was first produced in 1904 [11]. To that end, ARG is truly the first molecular imaging technique used for the localization of radioactivity in biological specimens. Fifty years later, Dziewaitkovski used β radiation to investigate the localization of compounds in biological samples [12]. This was followed by the development of the WBA technique by Ullberg in 1954 [13], who pioneered the technique by administering ^{35}S -penicillin to mice followed by freeze embedding them in water-soaked cotton using dry ice. He then sectioned their entire body bodies using a microtome in a walk-in freezer. The whole-body sections he produced were then exposed to X-ray film, which produced the autoradiographs that revealed the tissue distribution of drug-derived radioactivity. Methods for sectioning the whole bodies of laboratory animals were also developed and included the use of dry-ice-cooled microtomes [14], grinding down frozen carcasses [15], abrasion of resin-embedded carcasses [16], thick sectioning using a circular saw [17], and, finally, the development of a large microtome held inside a chest freezer [18]. Leica Microsystems, Inc. (Nussloch, Germany) began manufacturing commercially available large format cryomicrotomes and remains the leading provider of large cryomicrotomes used for WBA.

Quantitation of autoradiographs was the next challenge for pioneering macroautora-diographers. Berlin and Ullberg [19] and Kutzim [20] made the first attempts to quantify tissue concentrations in autoradiographs using early image analysis techniques. Unfortunately, the results achieved were only semiquantitative, but in the following years (1974–1987), several investigators [21–26] researched methods to better determine quantitative data from autoradiographs with limited success because of the inherent nonlinearity of film. Also during this time, Schweitzer [27] developed an image calibration method using ^{14}C -spiked blood standards at concentrations that bracketed the sensitivity of phosphor imaging plates. This robust technique continues to be used by many investigators today. Luckey revolutionized WBA in 1975 by developing and patenting phosphor imaging technology or radioluminography [28], which provided digital images from whole-body sections within days. Most importantly, these images enabled the direct determination of quantitative tissue concentrations over four to five orders of magnitude. Technical validation of the phosphor imaging instrument and QWBA methods, which more completely described the principals, specifications, and limitations of the instrumentation and QWBA, was published in 2000 [29].

In 1994, a group of autoradiographers in the pharmaceutical industry formed the Society for Whole-Body Autoradiography (SWBA) whose mission was to promote the use of QWBA over traditional organ dissection homogenate methods to determine tissue distribution of new drugs. Further work parameterized quantitative aspects to meet stringent bioanalytical expectations [30–35]. In 1990, a Japanese collaboration of >20 companies proposed that QWBA should replace the use of traditional dissection and LSC assay to determine true tissue distribution during the drug development [36]. Dr. Yasuo Ohno of the National Institute of Health Science (Tokyo, Japan) concluded his presentation at the 1997 meeting of the SWBA by stating that the Japanese Ministry of Health and Welfare would accept QWBA data in lieu of traditional organ

dissection distribution studies for the approval of new drugs as long as the procedures were appropriately validated. Today, pharmaceutical companies have almost entirely eliminated the use of dissection studies to determine the definitive tissue distribution of new pharmaceuticals, and these studies are now routinely submitted to regulatory agencies.

In addition to ARG and autoradioluminography, direct nuclear imaging technologies were also developed. These instruments utilize ionization chambers and different imaging technologies [e.g., scintillating sheet, charge coupled device (CCD) camera] and were first developed by Jeavons in 1983 [37]. Today's instrument consists of a parallel plaque avalanche chamber, which is based on the invention by Charpak in 1989 [38]. These instruments (Beta Imager and Micro Imager), which are currently sold by Biospace Lab (Paris, France), also image radioactivity in whole-body and individual tissue sections and have the ability to acquire quantitative images in real time. These instruments have proved most useful in drug discovery because they are capable of dual isotope analysis and provide data relatively quickly. However, relatively few sections can be analyzed at one time, and the instruments require regular and careful maintenance.

The key strength of the QWBA technique is its ability to provide true tissue distribution of radiolabeled test articles in a relatively unadulterated, *in situ* sample. Phosphor imaging has also been shown to be a very robust yet sensitive technology for the quantification of radioactivity in whole-body sections. Its wide linear detection range (four to five orders of magnitude) and sensitivity that can reliably quantify ~45 dpm distributed over an area of 0.5 cm² far exceed those achieved by LSC for similar sized samples. Phosphor imaging is also able to image the relatively weak energy of ¹⁴C and ³H, which, fortunately, are also long-lived isotopes, so that drugs and metabolites with very long half-lives can be tracked in the body of animals over years. This is not possible using the relatively short-lived isotopes used for *in vivo* positron emission topography (PET) and single photon emission computed topography (SPECT) imaging, which utilize special isotopes with half-lives generally much less than one day. In general, QWBA provides a much higher quality data set than that yielded by organ dissection and homogenate assay by providing concentration data on all tissues, not just those chosen for typical dissection studies, which eliminates the possibility of missing organs that may have high concentrations. The images can also be reviewed and analyzed at any time so that if an issue arises after the tissue distribution has been completed then investigators can go back, review, and quantify the nonroutine tissue(s) of interest.

QWBAs does, however, have several limitations that need to be considered. One of the major limitations of QWBA is its inherent nonselectivity, which is true for all radiolabeled studies. The actual molecular identity of the radioactivity signal detected may be due to unchanged parent drug, one of many metabolites that have retained the radiolabeled portion of the molecule, and/or degradation products. In addition, QWBA tissue sections are typically dehydrated to facilitate further processing, which results in the loss of volatile metabolites. Another limitation of QWBA is that it is difficult to evaluate short-lived isotopes, such as those used for radiopharmaceuticals, due to the processing time required, although it is possible to alter the processes to obtain data more quickly, but it requires special attention. For example, when using ⁹⁰Y, ¹¹C, or ¹⁸F as the radiolabel, which have half-lives of 2.67 days, 21 min, and 60 min, respectively, the frozen "wet" sections may need to be exposed to imaging plates

immediately and while under freezer conditions. Despite these technical challenges, Kaim *et al.* [39] were able to demonstrate that the uptake of ^{18}F -fluoroethyl-L-tyrosine (^{18}F -FET) in nonneoplastic inflammatory cells in an experimental soft tissue infection model was lower than that of ^{18}F -fluorodeoxyglucose (^{18}F -FDG), and they predicted a higher specificity for the detection of tumor cells using ^{18}F -FET.

Cost of instrumentation is another limitation. The instrumentation for QWBA is relatively expensive, and highly trained technicians are needed to perform the processing and analysis. QWBA is also limited, in that it cannot adequately provide data at the microscopic level because of the freezing technique. Despite the “snap freezing” techniques used, the freezing of all tissues is too slow to prevent cellular damage due to ice crystal formation. This makes histological receptor localization/staining and cellular identification difficult. Therefore, alternative methods are needed to evaluate cellular distribution and receptor occupancy.

Other general considerations for both dissection and QWBA tissue distribution studies include the radiochemical purity of the test compound, the radioactive dose, and methods of euthanasia. Generally, impurities should account for less than 5% of the material, and so the radiopurity of test articles should be greater than 95%. The use of anesthesia and the method of euthanasia can also affect the tissue distribution of any test article and should be carefully considered. For example, it is commonly thought that CO_2 alters the permeability of the blood–brain barrier (acidosis) and therefore alters normal brain penetration. Thus, euthanasia by CO_2 inhalation may not be a good technique to use if the objective is to study brain penetration. Likewise, euthanasia by exsanguination will undoubtedly have an effect on tissue distribution due to the massive fluid changes that take place in the body during this process [7].

13.4.2 Whole-Body Autoradiography in Drug Discovery

New initiatives in research, such as combinatorial chemistry, expanded compound libraries, parallel syntheses, and high throughput biological screening, have resulted in the generation of large numbers of compounds as putative drug candidates at pharmaceutical companies. The net result has been and will continue to be an increase in the number of drug candidates recommended for successful development. However, to increase the likelihood of developing a new drug, adequate screening for metabolic and PK liabilities during the early discovery process have become mandatory and efforts and cost to evaluate relevant metabolic characteristics of each new chemical entity (NCE) have increased substantially. It is, therefore, critical to reevaluate the current utilization of new technologies and the role of drug metabolism studies to support the discovery of NCEs. More sensitive and novel detection systems have made this process less cumbersome than in previous years. PK screening, drug stability studies, evaluation of metabolites, cytochrome P450 (CYP) involvement, enzyme induction and inhibition, and excretion studies play a major role in the drug discovery process. However, notably absent were tissue distribution studies, especially those conducted using WBA, which before the early 1980s demanded many resources and required a long time to achieve results (4–10 weeks). Quantitation of the autoradiographic images was also difficult because of the limited linear response of the films used to capture the autoradiographic images. However, within the last 15 years, the established methods of WBA have been combined with phosphor imaging technologies, which now provide reliable, quantitative tissue distribution information for

radiolabeled drug discovery compounds. This information can often be obtained within two weeks of dosing. WBA has also been used to answer pivotal questions regarding tissue PKs, routes of elimination, drug–drug interactions, drug localization, clearance, tissue targeting, solubility and formulation issues, routes of administration, tumor and brain penetration, interspecies comparisons, and tissue retention.

13.4.2.1 Brain and Cerebrospinal Fluid Penetration. A common clinical surrogate marker for central nervous system (CNS) penetration of drugs is the plasma to CSF concentration ratio [40]. However, unless this model is validated for each compound, it can be misleading when predicting the extent of CNS penetration of a particular compound. Discrepancies between CSF and CNS penetration can result from functional and structural differences between the blood–CSF and blood–brain barriers (i.e., permeability and surface area differences), variable diffusion of compounds from CSF into CNS tissue, and bulk CSF flow kinetics [41]. Numerous studies performed by preclinical PK laboratories have shown that many drugs get distributed differently into CSF and the brain [42,43]. Despite the evidence, which has demonstrated clear differences between CSF and CNS drug levels, the HIV literature contains many comparisons of CNS permeability of various therapeutic agents based on their relative CSF concentrations. Figure 13.2 shows the WBA results obtained using two different compounds that were being developed to treat HIV-1 [40]. The images clearly show different tissue distribution patterns between brain and CFS levels of drug-derived radioactivity. Thus, drug-A-derived radioactivity distributed preferentially in the CNS, whereas drug B distributed into the CSF but not in the brain tissue. This comparison revealed that there was no correlation between the distribution of drug-derived radioactivity in CSF and brain levels. Although the radioactivity observed in both compartments does

Figure 13.2 Cerebrospinal fluid (CSF) and brain penetration comparison in rats. Whole-body autoradiographs reveal differential distribution of drug-derived ^{14}C between brain and CSF of rats treated with different compounds. The comparison shows that drug levels measured in the CSF do not necessarily predict brain penetration and such models should be appropriately validated before making this assumption. (a) A brain with high concentrations of drug-derived radioactivity in the CSF but absent in the brain tissue. (b) An opposite situation to that in (a) Both are small molecule drugs that were expected to penetrate the brain because of high lipophilicity.

not discriminate between parent drug and/or its metabolites, the unequal distribution observed in all cases strongly suggested that each compound needed to be individually evaluated before making the assumption that levels of parent compound are distributed equally between CSF and brain.

13.4.2.2 Drug–Drug Interactions. Drug–drug interactions are a concern to drug developers whenever the potential exists for the coadministration of two drugs. It is, therefore, often valuable to know whether or not the drug(s) in question will change the disposition of the coadministered drug. An example is presented in Fig. 13.3, where a ^{14}C -labeled compound being developed to treat cancer was examined using WBA [40]. In this study, a single dose of the compound was administered alone (Fig. 13.3a) or coadministered with either 1-aminobenzotriazole (ABT) (Fig. 13.3b) or LY335979 (Fig. 13.3c). ABT is a known inhibitor of the cytochrome P450 metabolizing enzymes [44], the latter of which is responsible for the metabolism of the cancer drug being studied. LY335979 is a potent inhibitor of the transporter protein P-glycoprotein (Pgp) [45] for which the cancer drug was a substrate. Figure 13.3b shows that the pretreatment of animals with ABT resulted in reduced levels of radioactivity in the brain, whereas the use of LY335979 resulted in an enhancement of the radioactivity (Fig. 13.3c) in the brain as compared to the control (Fig. 13.3a). The results of this study suggested that the metabolites, but not the parent compound, of the drug contributed most to the amount of drug-derived radioactivity observed in the brain. This type of finding could have significant impact on the interpretation of *ex vivo* receptor autoradiographic binding assays performed to investigate the pharmacology of the compound in the CNS. Additionally, the study revealed that brain, and theoretically tumor penetration, could be improved by using LY335979. Similar studies with amprenavir [46] revealed an enhancement of concentration of the radioactivity in the brain of mice pretreated with GF120918, which is another potent Pgp inhibitor [47]. These examples show the potential of using known drug–drug interactions to study all types of toxicological, physiological, and pharmacological mechanisms of action, as well as PKs.

13.4.2.3 Melanin Binding. Melanin is a compound responsible for coloration in pigmented animals but is absent in albino animals, such as the Sprague Dawley (SD) rat, which is widely used in toxicology studies. Melanin is found in pigmented skin; choroid plexus and meninges of the CNS; the pigmented epithelial layer of the retina of the eye, such as in Long-Evans (LE) rats [48]; and in nerve cells of primates [49] and amphibians [50]. Many lipophilic drugs with pK_a values above 7 bind to melanin; however, the toxicological consequence of this binding has been debated for many compounds in the literature [51]. Structure–activity relationship studies using WBA for melanin binding as a function of various other physicochemical characteristics showed a correlation with volume of distribution, $\text{Log } P$, pK_a , and binding energy in pigmented rats. Strongly basic structures such as piperidine and piperazine moieties and other amines showed potential for retention in the ocular melanin [52]. Chloroquine, ofloxacin, norephedrine, and diazepam bind to synthetic melanin with varying affinity [53]. Diazepam, flunitrazepam, and Ro-5-4864 are known to induce melanogenesis [54]. Covalent binding of drugs to melanin is rare; however, its polyanionic nature and high content of carboxyl and semiquinone subunits facilitates noncovalent binding with many drugs. Although melanin binding of NCEs is not predictive of toxicity, it may prohibit the conduct of human radiolabeled studies where prolonged exposure of

Figure 13.3 Tissue distribution of an anticancer drug after the application of known drug–drug interactions. (a) The tissue distribution of drug-derived radioactivity after a single oral dose of an anticancer drug. (b) The effect of the coadministration of 1-aminobenzotriazole, which is a potent inhibitor of the CYP450 class of metabolizing enzymes, on the tissue distribution of the drug-derived radioactivity after a single oral dose of an anticancer drug. (c) The effect of the coadministration of LY335979, which is a potent P-glycoprotein inhibitor, on the tissue distribution of the drug-derived radioactivity after a single oral dose of an anticancer drug. (See color insert.)

pigmented tissues, especially the eye, to radioactivity could pose a health risk [55]. QWBA in pigmented rats often provides the first evidence of melanin binding of new drugs because melanin binding is not routinely assayed by other means in drug discovery and development. Figure 13.4a shows a SD rat autoradiograph obtained at 2 h after a single administration of a ^{14}C -labeled compound and shows wide tissue distribution of the drug. Figure 13.4b, which is an autoradiograph of an albino rat that

Figure 13.4 Melanin binding. Whole-body autoradiographs reveal tissue distribution of a ^{14}C -labeled drug in albino and pigmented rats. (a) A Sprague Dawley rat at 2 h post dose shows wide distribution of drug-derived radioactivity. (b) A Sprague Dawley rat at 96 h post dose shows limited distribution of drug-derived radioactivity and, notably, no radioactivity in the eye. (c) A pigmented Long-Evans rat at 72 h post dose shows limited tissue distribution of drug-derived radioactivity and, however, a high concentration of radioactivity in the eye, which is due to melanin binding.

was prepared for WBA at 96 h after a single dose, shows the absence of drug-derived radioactivity in the ocular tissues. Figure 13.4c shows the binding of drug-derived radioactivity in the pigmented skin and uveal tract of the eye of a pigmented LE rat at 72 h after a single oral dose. Although this compound did not produce any toxicity related to melanin binding, the predicted exposure to drug-derived radioactivity in humans during a proposed human ^{14}C metabolite identification study was shown to be a cause for concern.

The neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) causes selective destruction of melanin-containing monoaminergic neurons of the brains in primates [49] and amphibians [50]. MPTP is metabolized by monoamine oxidase type B to 1-methyl-4-phenylpyridine (MPP^+), which is known to bind to neuromelanin with high affinity and causes cell death and neurochemical features of Parkinson's disease.

The antimalarial drug chloroquine, which also has high affinity for melanin, competitively inhibits the binding of MPP^+ to neuromelanin in monkeys and provides a protective effect against motor abnormalities [56]. Such distribution studies could be monitored easily by WBA. MPTP-related toxicities were not seen in rodents that lack neuromelanin. The pigmented cells acted as depots for drug and/or metabolites, which results in toxic cytoplasmic concentrations causing nerve cell death. Similar melanin-binding studies have also been reported for ^{14}C - N - N' -dicyclopropyl-methyl-piperazine-dichlorohydrate in cynomolgus monkeys [49] and ^3H -aflatoxin in pigs [57].

13.4.2.4 Enzyme Induction/Inhibition. The induction and/or inhibition of drug-metabolizing enzymes by NCEs is a concern in drug development because it can effect the disposition and thus activity of the drug being developed and/or coadministered drugs [58]. The enzyme induction or inhibition caused by a compound may be a benefit, liability, or nonissue to the clinical use of the drug. For this reason, the drug's ability to induce or inhibit metabolism must be considered. WBA has been used to investigate the effects of enzyme induction by the compound on the tissue distribution and PKs of drugs [40]. Figure 13.5 demonstrates the effect of enzyme induction on the tissue distribution of a ^{14}C -labeled drug 24 h after a single oral administration (Fig. 13.5a) and 24 h after the last day of five days of single daily oral administration (Fig. 13.5b). In this instance, enzyme induction was known to occur *in vitro* and *in vivo*, but the actual effect on targeted tissues was unknown. The levels of drug-derived radioactivity in all tissues were lower in the induced animals (multiply dosed) than those of single-dosed animals. Apparently, induction of CYPs led to increased metabolism and excretion of metabolites via bile. This type of study can provide investigators with

Figure 13.5 Enzyme induction/inhibition and tissue distribution and PK. (a) Whole-body autoradiograph of drug-derived radioactivity in a Sprague Dawley rat at 24 h after a single oral dose of a ^{14}C -labeled drug. (b) Whole-body autoradiograph of drug-derived radioactivity in a Sprague Dawley rat at 24 h after the last of five daily oral doses of the same drug (days 1–4 administered unlabeled drug, day 5 administered ^{14}C -labeled drug). The data obtained at 24 h post dose showed that the elimination after multiple dosing was more rapid than that after a single dose and thus tissue exposure was notably lower. (See color insert.)

important information regarding exposure to target organs/tissues after multiple daily dosing and, in some cases, may require alteration in the dosing regimen in the clinic. The effect of enzyme inhibition on the tissue disposition of NCEs can also be studied by observing the effects that coadministered drugs have on the distribution of NCEs.

13.4.2.5 Tumor Penetration. WBA has been an invaluable tool in cancer research for its ability to provide a visual depiction of tumor penetration, as well as providing a snapshot of general tissue distribution in both tumor and toxicological animal models. Figure 13.6 shows the distribution of a ^{90}Y -labeled anticancer agent, which was administered orally to transgenic mice that expressed human mammary tumors. This study, which was performed very quickly (within three days) because of the short half-life of the radioisotope, showed excellent tumor penetration as well as retention in the tumor versus normal tissues [40]. Importantly, since this technique involves examining all

Figure 13.6 Tumor penetration model. Whole-body autoradiographs of tumor-bearing mice that were administered a single IV dose of a ^{90}Y -labeled anticancer drug and sacrificed at (a) 2 h or (b) 24 h post dose. Insets show close-ups (enlarged $\times 4$) of the tumor in each mouse. WBA revealed that high levels of drug-derived radioactivity remained in the tumors for up to 24 h post dose, while radioactivity in normal tissues declined to lower levels. (See color insert.)

other major tissues, distribution of the compound to other potential target organs, such as pancreas, liver, and stomach, can be monitored.

In other oncology studies conducted, mice implanted with ovarian Oca-1 tumors and dosed with ^3H -paclitaxel (TXL) in Cremophor EL and alcohol vehicle or ^3H -poly(glutamic acid)-paclitaxel (PG-TXL) showed that the better efficacy of PG-TXL over TXL in inhibiting tumor growth due to the broader distribution of TXL and/or its metabolites in tumors when dosed as the macromolecular conjugate [59]. The concentration of free and conjugated TXL was determined by excision and processing of tumors in mice in a parallel study. By WBA, the distribution of radioactivity in the tumor was determined to be initially located in the periphery of tumors on day 1 and was homogeneously distributed into the center of the tumor by day 6. Similarly, a comparison of intratumoral injection of mitomycin C and its dextran conjugate in rats bearing Walker 256 carcinosarcoma, by WBA, showed that while mitomycin C cleared the tumor rapidly, the intratumor clearance was greatly retarded when it was conjugated with dextran [60].

13.4.2.6 Fetal Penetration. WBA can also be used to address questions about placental transfer and tissue retention because clear pictures of the distribution to various organs within the fetus can be investigated. For example fetal penetration of [^3H]deramciclane, an anxiolytic agent, after IV and oral administration in rats was not observed [61], which was a useful finding in animals and was used in the package labeling to support safe administration in pregnant women. On the other hand, [^{14}C]olanzapine [62], *Fusarium* mycotoxin zearalenone [63], and chloroacetonitrile [64] have been shown to cross the placental barrier in rats by WBA, which posed a potential safety liability for development of these drugs.

13.4.2.7 Formulation Selection. Formulation changes are sought to bring about desired alterations in the absorption and tissue distribution and also to avoid certain side effects. QWBA was used to determine that a submicron lipid emulsion of the drug tirilazad over an aqueous solution helped to avoid venous irritation without sacrificing PKs and tissue distribution in rats [65]. WBA of holmium-166 (^{166}Ho) chitosan complex, a radiopharmaceutical for cancer therapy, after intrahepatic administration to rats and mice, showed that the drug was not distributed to tissues but was retained at the site of administration [66].

13.4.2.8 Metabolism/Covalent Binding. The use of WBA coupled with other procedures can be adopted for studying metabolism and covalent binding of compounds to specific tissues that show retention of radioactivity. Notable examples include the use of (i) whole-body sections where specific areas of the sections were punched to obtain tissue samples that were subsequently extracted and analyzed for metabolites [67] using mass spectroscopy analysis and (ii) freeze-dried tissue sections from a lamb, which was dosed with ^3H -aflatoxin, were extracted successively with 5% trichloroacetic acid (TCA), 50% ethanol, 99.5% ethanol, heptane, and water and then dried and imaged to study the distribution of nonextractable radioactivity [68]. These studies enabled the differentiation of metabolites and tightly bound compounds in tissues. New technologies such as the Advion Nanomate[®] instrument that facilitates the extraction and collection of compounds from whole-body sections can make this process easier. There are other examples of similar analysis that used the residual frozen animal carcasses after WBA samples were collected [64,69,70].

Figure 13.7 Retention in rat tissues. Whole-body autoradiographs of two rats given similar IV doses of a ^{14}C -labeled compound and were sacrificed at (a) 0.5 and (b) 48 h post dose. Autoradiographs showed little or no decline in the amount of drug-derived radioactivity at 48 h post dose, which suggested that the compound was retained in the tissues of the rat.

13.4.2.9 General Tissue Retention. WBA can also be used to determine sites of retention of drug-related material when the mass balance of administered material in excreta samples is low and/or when unusual plasma PK is observed. In an early mass balance study in our laboratories, the total radioactivity of a new compound was not recovered from rats 24 h after IV administration of the compound, with only small amounts of radioactivity recovered in urine, feces, and bile [40]. QWBA was used to identify the unknown sites of possible tissue retention, and it showed that the compound was widely distributed at both 0.5 and 48 h post dose (Fig. 13.7) and tissue levels of radioactivity were essentially unchanged from 0.5 to 48 h post dose. Data suggested that drug-derived radioactivity was retained in the tissues of the rat, while being rapidly cleared from the systemic circulation. The observed tissue retention raised concerns of possible toxicological problems, especially in liver, kidney, heart, and lungs where concentrations were highest. In another study, IV administration of [^{14}C]-D- or -L-serine to rats led to the detection of accumulation of radioactivity in the corticomedullary areas of kidneys, which suggested a possible link between the observed acute necrosis of the renal proximal tubules and administration of large doses of D-serine [71].

13.4.2.10 Application of QWBA to Therapeutic Peptides and Proteins. ^{125}I -labeled proteins and peptides are being used for QWBA analyses to study tissue distribution and PKs in the biotechnology arena. Increasingly, regulatory agencies are asking for this information, as data gleaned from these studies have helped them to better understand and select their compounds in drug development. Although the *in vivo* stability of ^{125}I on most large molecule xenobiotics is difficult to assure, the data generated from these studies can be useful. Semiquantitative data can be obtained with confidence when the *in vivo* stability and amount of free ^{125}I circulating in the body is characterized.

Currently, ^{125}I ARG is most often used to provide a quantitative method for determining tissue distribution of large molecules because it is either not possible or extremely expensive to radiolabel these molecules with ^{14}C or ^3H . Although ^{35}S can

be used in some instances to label large molecules, the synthesis and location of the radiolabel can be difficult, but the resulting stability of the radiolabel, image resolution, and quantification are an improvement over ^{125}I labeling, which is much more instable. The stability of ^{125}I labeling on large molecules is subject to cleavage *in vivo*, which often results in relatively high concentrations of free ^{125}I . The determination of drug concentrations in tissues using ^{125}I labeled molecules must be considered as semiquantitative because of the inevitability of measuring free ^{125}I along with the test article. Thus, care must be taken when interpreting tissue concentrations of ^{125}I -labeled compounds for the thyroid, stomach, kidneys, mammary gland, salivary gland, thymus, epidermis, and choroid plexus [36]. These organs contain a sodium-iodide symporter that are involved in the organification and/or elimination of free ^{125}I [72,73] and often have very high concentrations of free and/or organified ^{125}I , which is not drug related and thus provide misleading results. Most iodopeptides are absorbed intact through the intestinal tract, but once in the blood stream, deiodination can occur to varying degrees depending on the labeling [72,74]. Iodide has a volume of distribution that is about 38% of body weight and is mostly extracellular. In humans, total plasma iodide clearance is about 12% per hour (rate = 45–60 mL/min) and thyroid clearance varies widely depending on dietary intake and can be as low as 3–4 mL/min [73,74]. These data must be considered when considering tissue quantification and imaging with ^{125}I -labeled biotherapeutics. Finally, regulatory agencies have begun requesting that biotechnology companies show the ADME characteristics of large molecules. This can be a challenge in some cases because large molecules are usually not easily labeled with conventional more stable isotopes (e.g., ^{14}C) and their metabolism is often similar to that of endogenous proteins and peptides.

Administration of nonradiolabeled sodium iodide to test animals before giving the ^{125}I test is one way to reduce the uptake of free ^{125}I by shunting free ^{125}I to the kidneys to increase the rate of clearance and reduce the effect on tissue quantitation. Furthermore, the concentrations of free ^{125}I in the body must be characterized to better understand the true drug-derived concentrations in tissue and this can be done by using protein precipitation with TCA protein precipitation of plasma and determining the ratio of protein-precipitable ^{125}I versus free ^{125}I [73]. This ratio can then be used to correct tissue concentrations obtained using QWBA. Further analysis to determine the radiostability of ^{125}I -labeled compounds in tissues may be done using gel electrophoresis, thin-layer chromatography, ELISA, and/or specialized mass spectroscopy techniques. To these ends, tissue quantitation of drug-derived radioactivity using ^{125}I and QWBA or gamma counting techniques can, at best, be considered as a semiquantitative technique, albeit one of the only practical techniques currently available.

Skofitsch *et al.* [75] used ^{125}I -galatin to identify specific binding sites in rat brain using ARG, which is one of the earlier examples of the use to study large molecule distribution. As many types of antibodies are being developed to treat cancer and other diseases, ^{125}I -labeled antibodies have been used increasingly to evaluate tumor penetration and localization. Figure 13.8 shows such an example where QWBA demonstrated localization in the highly vascularized portions of the tumor. Targeting of drugs to necrotic portions of a tumor can be studied by QWBA since differences in uptake between different regions of tumors can be observed, whereas this information could not be obtained through a typical excision/homogenization experiment. The increased interest in delivering oligonucleotide therapeutics including small interfering RNAs [small nuclear ribonucleic acid (snRNA)] to their desired site of action has prompted

Figure 13.8 Tumor penetration and distribution. ^{125}I -Peptide distribution in different tissue regions of tumors are shown. Note the higher concentrations (darker regions of autoradioluminograph) in the more vascularized areas of the tumor (a) as compared to the regions that show a high concentration in the solid tissue regions (b). (See color insert.)

distribution studies of these entities. ^3H or ^{14}C labels can be incorporated for QWBA investigations.

13.4.3 Whole-Body Autoradiography in Drug Development

Most often, QWBA is used during the drug development stages and to support regulatory submissions. The data are used to show tissue PKs and to predict human radiation dosimetry for the human radiolabeled ADME studies. A routine tissue distribution performed using QWBA typically evaluates 35–40 tissues using 6 or more time points designed around known plasma or tissue PKs.

13.4.3.1 ADME Regulatory Studies. The design of tissue distribution studies for drug development and regulatory submission has changed since QWBA has been implemented [36]. In the past, the number of time points used was rarely sufficient to determine reliable tissue PK parameters. Most notably was the determination of the $T_{1/2}$ of drugs in individual tissues. This has implications for predicting the tissue PK and pharmacodynamics of drugs as well as the exposure of human tissue to radiation during human radiolabeled studies conducted to determine human excretion patterns and identify metabolites. Albino strains are most commonly used for whole-body autoradioluminography (WBAL) because they are used most often as the toxicology model; however, pigmented animals are often included in studies conducted to support human radiodosimetry predictions in order to gain exposure information in pigmented tissues such as the skin and eye. When pigmented and albino rats are used, investigators must be aware of strain differences, especially to physiological differences related to drug metabolism and brain physiology [76,77]. Large animals such as rabbits, dogs, and monkeys are also frequently performed for drug development purposes, especially when the species demonstrates plasma kinetics similar to humans. Furthermore, samples of blood, plasma, bile, urine, and feces may be collected from the animals on the QWBA

studies and analyzed by other means such as liquid chromatography/mass spectrometry (LC/MS) or radio-HPLC to provide information regarding metabolism. Investigators and regulatory agencies have embraced these approaches and currently recommend that tissue distribution studies be conducted using validated QWBA methods [78].

Another important consideration is the choice of using a single dose or multiple doses, and a uniform guidance regarding this has been issued by worldwide regulatory agencies [78,79]. They state repeated dose distribution studies may be appropriate when

1. A single-dose distribution study suggests that the apparent half-life of the test article and/or metabolites in organs/tissues significantly exceeds the elimination half-life in plasma and is also more than twice the dosing interval of toxicology studies.
2. Steady state concentrations of the compound/metabolite in circulation of PK or toxicology studies are higher than those predicted by a single-dose kinetic study.
3. Critical histopathological findings of safety studies are observed that would not be predicted by a short-term toxicology and/or single-dose distribution or pharmacology study. The focus of the distribution study should be on those target organs.
4. The pharmaceutical is being developed for site-specific targeted delivery.

The regulatory guidelines and requirements for the designs are less specific but state that the study design should utilize radiolabeled compounds or alternative methods with sufficient sensitivity and specificity to provide quantitative data. They also suggest that metabolites be surveyed as well as the parent molecule [80].

13.4.3.2 Studies for Human Radiation Dosimetry Predictions. Human radiolabeled drug studies are often performed as part of phase II clinical trials to determine human metabolism and PKs of new drug entities. ^{14}C - and ^3H -labeled compounds are routinely used in human beings to determine ADME characteristics of NCEs in human subjects. In order to perform these studies, a sponsor needs to provide a prediction of radiation exposure to tissues and/or organs in the body that might result from the administration of a radiolabeled drug. Clinical investigators must assure that the dose of radioactivity associated with the radiolabeled drug will not be harmful to volunteers and falls within acceptable exposure ranges before radiolabeled drug studies can be performed in humans. The Food and Drug Administration (FDA) also requires that pharmaceutical companies perform a prediction of human exposure to radioactivity as a result of the administration of radiolabeled test compounds.

Dosimetry predictions rely on mathematical models and known radioactive tissue/organ concentration profiles and/or excretion patterns, which are obtained from QWBA or “cut and count” tissue distribution studies. The FDA and the International Commission on Radiological Protection (ICRP) have set allowable limits for exposure of radiation involving the administration of single doses of radionuclides to human volunteers. The FDA has limits of 3 rem, which is a measurement of equivalent radiation exposure to whole body and critical organs, and 5 rem to other organs. The ICRP Category IIa effective dose upper limit has been set at 1 mSv, which is another unit of radiation dose equivalent. Recommendations for the methods to determine human and dosimetry predictions have been published by the FDA and ICRP. However, the calculations and data obtained from the various methods can produce different predictions

of radiation exposure and can present problems for clinical review boards considering the approval of proposed human radiolabeled drug studies [81].

Several mathematical prediction methods and calculations have been proposed over the years, but most pharmaceutical companies rely on guidance from the ICRP and those proposed by the Medical Internal Radiation Dose (MIRD) Committee of the Society for Nuclear Medicine [82]. Representatives of the FDA have also published a guidance on the prediction [56]; however, the FDA initiated an updated guidance in 2009 [78]. Additionally, several textbooks have been written over the years, and the basic calculations have not changed much since the early 1960s [83]. However, the equations suggested by the MIRD Committee have been revised over the years and two software packages called MIRDose and OLINDA, which were based on the MIRD equations and developed by the Oak Ridge National Laboratory, were created to aid in dosimetry predictions. These softwares utilize mean residence times (MRTs) obtained from the animal tissue/organ distribution information obtained from earlier studies to predict the radioactive exposure to humans given a radiolabeled NCE or other radioactive substances. MIRDose provides predictions for whole-body exposure and major organs only. MIRDose does not calculate the exposure for many other tissues, and for this reason, its utility for dosimetry is limited.

The equation referenced by Dain *et al.* [56] was originally developed by Marinelli [84] and then refined, to account for animal data, by Hendee [85]. The calculations and methods for predicting human dosimetry presented by the ICRP appear to be related more to industrial radiation workers and the general population and not necessarily focused on clinical radiolabeled drug studies.

The literature on radiation exposure predictions often refer to and consider the $T_{1/2}$ and/or MRT of the isotope used to label the test compound but not necessarily the biological $T_{1/2}$ or MRT of the test article, which may vary considerably from the isotope. This has presented a challenge for pharmaceutical researchers who need to determine what calculations and methods can be used along with the detailed tissue distribution data offered by QWBA.

Anecdotal evidence suggested that there are misunderstandings about dosimetry and different dosimetry methods provide different estimates. A rodent tissue distribution study, which was designed to provide reliable tissue PK parameters by Solon [81], tested this hypothesis by choosing the following three sets of recommended calculations: (i) “Hendee–Marinelli” equation [56]; (ii) MIRD Committee, MIRD equation [86]; and (iii) ICRP recommendations (weighting factors for whole-body exposure [87]). The results showed that each method produced a different prediction of tissue and whole-body exposure. It was also observed that some equations (e.g., MIRD) were best designed for organ homogenate data, which are obtained from organ dissection/homogenate analyses, and do not readily account for the use of actual tissue concentrations. The equations also did not adequately consider allometric scaling from rodents to humans. Furthermore, the use of weighting was not appropriate for use on individual tissues but for determining the contribution of tissues to whole-body exposure only. A common practice among laboratories is also to use PK parameters that have been obtained from studies where reliable parameters cannot be obtained because of study designs that do not adequately capture time points. This results in unrealistic $T_{1/2}$ and AUC values that can grossly over or underestimate exposures. QWBA results have repeatedly shown that tissue concentrations often vary considerably within organs, thus predictions obtained by using organ homogenate data can greatly

under- or overestimate the actual tissue exposure to radioactivity (e.g., concentration found in the cortex and medulla of the kidney). This finding suggests that the current dosimetry methods may need to be revised to better utilize true “tissue” concentration data from QWBA studies for determining the tissue level exposure. This study showed the need to reexamine in detail the guidelines and methods being used to determine human ^{14}C dosimetry from administered radiolabeled drugs for human studies.

13.4.3.3 Postapproval Studies. QWBA has also been used to examine drugs after they have been approved for use to support marketing efforts and/or to address postapproval issues. Schweitzer *et al.* [88] investigated the distribution of [^{14}C] diclofenac sodium (Voltaren[®]), which is a drug that has been marketed for years, after a single oral administration in rats. These investigators showed that diclofenac preferentially distributed into the inflamed tissues and achieved exposures that were 26- and 53-fold higher in the inflamed neck and inflamed paws of treated animals than in control rats, while all other tissues in treated animals and control animals showed similar distribution and exposure. In this case, the study was done in response to a request from a project team and it also supported marketing efforts for the compound. It also provided for comparing the dermal penetration and distribution of future formulations that could improve exposure and efficacy.

13.5 MICROAUTORADIOGRAPHY

MARG provides pharmaceutical scientists with a high resolution tool to investigate spatial localization of radiolabeled drugs at a tissue and cellular level. MARG is especially good at providing insight regarding *in vivo* receptor binding in various cell types and has predictive value for specific drug targeting. In this respect, it has been used widely in academic settings to answer basic research questions and/or to support pharmacologic studies where it can provide important information on cellular mechanisms. MARG has applications in all areas of science, but this report discusses examples in drug metabolism, pharmacology, toxicology, and molecular biology.

The methods used by the author, which are described below, are based on the methods of Appleton [89] and Stumpf [90], but it is important to realize that there are many variations of the method presented in the literature. To begin, an animal is dosed with a radiolabeled substance (typically, ^3H , ^{14}C , ^{35}S , or ^{125}I), the animal is exsanguinated, and tissues are dissected and snap frozen in isopentane that is chilled in liquid nitrogen. The tissue is then cryosectioned at -20°C (or the optimal cutting temperature for a given tissue/organ), to obtain 4- to 5- μm thick sections. Then, under darkroom conditions, sections are thaw mounted onto dry glass microscope slides that have been precoated with nuclear photographic emulsion. The slides are placed into a light-tight box with desiccant and allowed to expose for an appropriate amount of time. The collection of sections onto dry slides is a key step developed by Appleton [91] and eliminates the possibility of diffusion of soluble compounds, which can happen during slide and section dipping into an aqueous emulsion. In contrast, the original Stumpf and Roth method [90] involved collection of the section into vials for freeze-drying, which required very careful section handling, was very time consuming, and prone to sample destruction. Following exposure, the slides are developed in a manner similar to developing photographic film before being stained using conventional histological

staining protocols. This may include immunostaining techniques that can provide positive colocalization of drug-derived radioactivity to known cell types, receptors, and/or other structures/markers for which antibody staining protocols exist [90].

There are several examples in the literature of investigators attempting to obtain quantitative data from MARG preparations. A few methods have been proposed to determine subcellular concentrations of drugs. These methods, which date back to the late 1960s, have been presented in books by Stumpf [90] and Baker [92]. One of the earliest methods, which was known as *restricted method*, was based on the analysis of structures of similar shape and size [93] and used to describe the distribution of silver grains in sections of ^3H -noradrenalin-labeled nerve terminals. A second “restricted method” was also based on the analysis of structures of similar shape but dissimilar sizes [94]. This method established a “universal curve” and required that the two-dimensional structures associated with radioactivity were of similar shape. An “unrestricted method” or “circle method” was developed by Williams in 1969 [95]. This tested the hypothesis that radioactivity was randomly distributed, and it ascribed values for relative concentrations. It also attempted to account for a lack of precision of the restricted models. A second “unrestricted method” known as the *hypothetical grain* method was developed by Blackett and Parry in 1973 [96]. This method has five stages that include (i) overlay screen preparation, (ii) collection of “hypothetical grains” and construction of a “crossfire” matrix, (iii) collection of real grain data, (iv) fitting of hypothetical and real grain data using chi-square, and (v) modification of the matrix until an “acceptable fit” is obtained. Each of these methods claimed to be able to estimate the number of molecules in subcellular regions if the specific silver grain yield (average number of disintegrations to produce one silver grain) was determined. Then, it was “theoretically” possible to determine the number of molecules in a cell or nucleus. The formulas must consider exposure time, specific activity, silver grain yield (dependant on uniform method conditions), section thickness, volume of the compartment, and “other parameters,” which are very difficult to control because of the various artifacts inherent in an inherently sensitive technique. High sensitivity techniques require extremely consistent and careful preparation, especially because the current MARG techniques rely on many manual and “artful” steps. The uniformity of the detection media (i.e., emulsion-coated slide) is unknown and not characterized in almost all examples in the literature. Tissue absorption of radioactivity is also rarely considered or characterized. The number of cells counted/quantified must be sufficient for robust statistical analysis. Background subtraction and variable background can invalidate results. There are no tissue section thickness quality control standards and/or internal calibration standards used in MARG. Changes in daily cosmic and background radiation can adversely affect an entire, several months long study. In short, most pharmaceutical researchers do not have the resources available to develop routine MARG procedures to enable and or prove that MARG is a quantitative technique, and thus its limited application to date.

13.5.1 History

The first microautoradiographic data were produced by Lacassagne in 1924 [97], which lead to further work by Bélanger and Leblond [98], who poured liquid photographic emulsion onto histological sections to reveal the location of radioactive substances in the tissues. Jofte and Warren in 1955 [99] revised that technique and dipped slides

into photographic emulsion, which gained wide use because of its ease of manipulation. This technique has survived the years and is sometimes used today. However, if diffusible radiolabeled compound are utilized, the results can be useless owing to the relocation of the radiolabeled substance, which produces telltale artifacts that can invalidate experiments and discourage investigators. During the 1940s, methods utilizing strips of dried emulsion were developed where the histological sample containing a radioactive substance was placed in direct contact with the dried emulsion strip for a finite exposure time. This method proved cumbersome because maintaining the precise position of the strip on the samples proved cumbersome during exposure, development, and staining. Often alignment could not be maintained, ending the entire process in failure. However, in 1964, Appleton [89] first developed the technique of collecting cryosections onto slides covered with strips of dried emulsion using a thaw mounting technique. This required tissue sectioning and collection to be conducted in a darkroom and under safelight conditions, which required a high level of skill.

The use of cryopreservation and cryosectioning remains critical to the study of diffusible substances because it maintains the spatial locale of the radiolabeled substance in the matrix, whereas liquid tissue fixation steps often solubilize and relocate diffusible test articles. However, when substances are tightly bound to cellular structures (e.g., receptor proteins), positive results may still be obtained from samples processed using conventional histology techniques. Further refinement of MARG techniques occurred during the 1960s by Caro [100], and shortly after that Stumpf and Roth [91] made additional improvements to establish receptor ARG as a more reliable technique. This established the basis for the current MARG techniques. Numerous elaborations on the techniques have been presented by different investigators [101], but the basic principals have remained unchanged for >40 years. Today, as in the past, the MARG technique is very difficult to master, which continues to hamper its use. Researchers must use caution when reviewing the literature and relying on articles that used the emulsion dipping technique and claim quantitative data. The conclusions may be questionable and disputed in some cases. Validation of the technique is lacking in most laboratories and results can be very subjective. This is due to the lack of thickness uniformity of both the tissue sections and the emulsion detection media used. Additionally, there are few, if any, instances where calibration and/or quality control standards have been co-exposed within the samples, which is the only way to clearly prove quantitation across different types of tissue samples.

13.5.2 Strengths and Limitations of MARG

The main strength of the MARG technique is the ability to provide researchers with a high resolution imaging tool for determining the cellular and to a certain extent subcellular, localization of radiolabeled compounds in animal tissues. It is also a very sensitive technique that can theoretically detect the actual number of molecules in a preparation [90], although those claims are difficult to substantiate, and so the technique is mostly used as a qualitative tool. ARG techniques can also be applied in specimens prepared for electron microscopy. However, because of the high degree of tissue processing, it does not lend itself to the localization of diffusible substances, which can be easily solubilized and relocated from tissue during fixation, infiltration, and embedding procedures; however, when the radiolabeled substance is stable in the tissues, such as DNA, RNA, structural proteins, and/or covalently or tightly bound substances, then

the technique can be very powerful and useful. *In situ* hybridization [102] is a good example of how molecular biologists have applied ARG techniques to reveal many aspects of cellular processes, which has been used for many years. Another strength of MARG is limited tissue samples processing and thus accurate capture of the localization of test articles in space and time. The main assumption is that exsanguination and dissection of the tissue samples used do not adversely effect localization of the radiolabeled test substance. Tissues can be removed and frozen relatively quickly and so qualitative localization is believed to be accurately reflected.

Several limitations have impeded the progress and wider use of MARG in drug discovery and development. These include the high rate and ease of artifact production and difficulties of tissue section collection under darkroom conditions. The processing time to obtain results by MARG is difficult to gauge as each tissue must be treated and evaluated differently, depending on how much radioactivity is present. The exposure time can take anywhere from days to weeks or even months to obtain optimal results. Technology may help to solve some of these problems if the detection media (e.g., emulsions) can be more uniformly produced and made to have inherently linear quantitation. It may also help to develop easier methods of collecting uniformly thick tissue sections that can be automatically mounted onto slides for processing, although this would be quite a challenge because of the varying matrices to be sectioned (e.g., hard bone, adipose, and eyes). Dependable micro-sized calibration and quality control standards that can be co-exposed with every section would also need to be developed to assure reproducibility of quantitation. Finally, the new methods would need to enable a significant reduction in the amount and types of artifacts that are produced. Currently, the following types of artifacts [90] must be controlled: (i) effects on emulsion by slight variations in light, humidity, temperature, tissue characteristics, fixation, freezing, chemicals, pH, developer, fixer, and miscellaneous debris in developer solutions; (ii) tissue condition (e.g., freezing technique, fixation, autolysis, sectioning temperature, improper section mounting); (iii) light leaks; (iv) latent image fading; (v) folding and shrinking of emulsion; (vi) positive chemography, which is exposure of the emulsion by endogenous chemical effects such as tissue enzymes; (vii) negative chemography; (viii) deviations of pH in processing fluids; (ix) pressure artifacts; (x) ice crystals on knife; and (xi) crystalline deposits from developing process. Some of these are more easily controlled than others, but together they require a high level of skill by the analyst to overcome. The current technique will remain qualitative and too daunting for routine use in pharmaceutical discovery and development until methods and/or technologies can be developed to better control for variables and artifacts. The lack of new developments in MARG methods has continued to make MARG an under-utilized technique in drug discovery and development, but when performed correctly, the results can be of utmost value in promoting a drug candidate and in answering some pivotal questions for pharmaceutical investigators.

13.5.3 MARG in Drug Discovery and Development

Despite the difficulty in mastering the technique and high risk of artifacts, MARG has made important contributions to drug discovery and development over the years and has provided insight into the localization of pharmaceuticals to support proof of concept studies, mechanisms of toxicity, efficacy, physiology of hormone action, and cell regulation. For example, MARG is useful to study skin penetration of various

compounds and is routinely used in the cosmetic industry, physiology research, pharmacology, and safety studies. Unilever has developed MARG techniques to examine skin penetration in different *in vitro* test models in rats, pigs, and human skin sample to demonstrate efficacy for consumer skin care products using MARG coupled with confocal microscopy and other techniques (Minter 2007, Personal communication). Linoleic acid (LA) is commonly used in cosmetics, but its *in vivo* human skin penetration characteristics were not very well demonstrated. However, in 2006, Rauvast and Mavon [103] used a unique, *in situ*, “virtual” microautoradiographic slide to examine transfollicular delivery of LA in human scalp. They combined their MARG data with an *in vitro* permeation experiment and compartmental analysis to show that most of the LA was localized to the hair sheath but none was present in the dermal compartment and that 10% of the total LA recovered was found in the stratum corneum and dermis after 6 h. This supported the notion that the diffusion of LA occurred by a transfollicular route. It also demonstrated the value of high resolution MARG for providing detailed cellular localization of the molecule. Skin receptor MARG techniques have also been used to study the absorption, penetration, and cellular localization of ^3H -Maxacalcitol, which is a vitamin D analog used for the treatment of psoriasis. Hayakawa *et al.* treated the dorsal skin of rats with a ^3H -Maxacalcitol ointment and examined skin exposed for periods of 0.5 through 168 h [104]. They discovered two routes of skin penetration; one via epidermal cell layers and the other via hair follicles. They were also able to distinguish very fine regions of cellular localization, which supported theories on the mechanism of efficacy. Young *et al.* [105] used ^{14}C -iodoantipyrine as a tracer to study intrarenal blood flow in nephrectomized rats, and they used their microautoradiographs and standards to determine blood flow rates. MARG provided a means to identify the morphological location of blood flow, and they concluded “that medullary blood flow was dependent on local prostaglandin production and is also influenced by sympathetic nervous supply.” Figure 13.9 shows an example of the distribution of ^{14}C -azidothymidine (^{14}C -AZT) in the glomerulus of a rat kidney after a single IV dose [36]. This example demonstrates the fine detail of localization that can be obtained with MARG. Both renal function and localization of various substances in the kidney have been studied by MARG. Another laboratory used *in vitro* MARG to show localization and density of atrial natriuretic peptide (ANP) in nephrectomy biopsy samples obtained from patients with renal disease [106]. These investigators used [^{125}I]- α -human (1–28) ANP and found localization in the glomerulus and tubular regions in the human biopsy specimens. They also observed that density of ANP binding generally decreased in patients with renal dysfunction and hypertension. Overall, though, their study established an *in vitro* MARG method to assess ANP binding in human biopsy specimens.

More recent work by Yamamoto *et al.* [107] used MARG in combination with immunohistochemistry, macroautoradiography, and PET to examine intestinal ulceration and healing in the rat. They used ^{18}F -FDG to examine ulcerations in the small intestine of rats, which were induced using indomethacin. MARG combined with immunohistochemistry showed an accumulation of ^{18}F -FDG in inflammatory cells as well as in granular tissue-forming cells, forming granulation tissue, and around ulcers. ^{18}F -FDG was also found to be present in proliferating intestinal crypt cells and intact intestinal tissue taken from indomethacin-treated and control animals. They concluded that ulceration could be visualized early by the prominent uptake of ^{18}F -FDG by inflammatory cells and by the formation of granulation tissue by cells in and around

Figure 13.9 Microautoradiography results of rat kidney after a single administration of ^{14}C -azidothymidine in a rat kidney after a single IV dose. The location of the drug-derived radioactivity is made apparent by the black specks that appear over the section. In this case, a high concentration of the drug is shown localized to the glomerulus. (See color insert.)

ulcers. This work also demonstrated the value of combining both *in vivo* and *ex vivo* imaging techniques, which provided robust data sets for analysis.

13.6 CONCLUSIONS

Molecular imaging has grown dramatically over the last 50 years, and most recently, *in vivo* imaging modalities such as PET [108] and fluorescence [109] imaging has captured the attention of scientists in drug discovery and development owing to the ability to visualize organ *in vivo* distribution in preclinical species. However, these new *in vivo* modalities have their limitations, such as relying on the use of short-lived isotopes as in PET imaging, which limits the ability to study tissue PKs over days or weeks or encountering issues with reliable quantitation due to background fluorescence and poor resolution, which occurs when imaging fluorescent tags *in vivo*. Additionally, the positron-emitting isotopes for PET and the fluorescent labels used can alter the structure and/or binding capabilities of molecules, thus rendering them ineffective at providing the needed information. The inability to distinguish between labeled drug, metabolite(s), and/or degradants is also a limitation of these modalities. However, with the recent developments in matrix-assisted laser desorption ionization mass spectrometric imaging (MALDI MSI), desorption electrospray ionization mass spectrometry (DESI), and secondary ion mass spectrometric imaging (SIMS) technologies, which rely on the use of whole-body sections, the ability to distinguish between the parent molecule and metabolites is possible. Unfortunately, these technologies have not

reached the point of being quantitative, which means QWBA is expected to remain the technique of choice for tissue quantitation. To these ends, *ex vivo/in situ* imaging modalities such as QWBA and MARG will undoubtedly be relied on for many years to come to provide the kind of detailed tissue distribution information required for drug discovery and development programs.

14.1 SUMMARY

Ligand-binding assays (LBAs) or immunoassays are the analytical method of choice for pharmacokinetic (PK) and immunogenicity assessment for biopharmaceuticals. As pipelines for this class of drugs are expanding, LBAs are revisited to address current scientific questions with this classic technology. Although immunoassays come in a vast variety, they share some similar concepts. Typically, the analyte of interest is captured out of a mostly unpurified solution using specific antibodies or receptors. Bound analyte is then detected with a labeled reagent either in a competitive or a sandwich format.

Since their earliest inception for the measurement of insulin, immunoassays rely on antibodies specific to the analyte of interest. These days, different capture and detection reagents are often used, for example, two different antibodies or a combination of target and antibody. In any case, reagent specificity, selectivity, and quality are keys to a successful LBA. Monoclonal antibodies and other recombinant technologies allow the generation of custom reagents to meet the requirements of most LBA methods.

Some advantages of immunoassays include their limited cost per sample, sensitivity, and lack of need for extensive sample purification. Disadvantages are the indirect readout that is inherent in the method, long lead times for optimal reagent generation, and the potential for interferences by the sample matrix, in particular, body fluids.

While the basic immunoassay schematic remained the same, recent technologic advancements addressed some of the downsides. Meso Scale Discovery (MSD)-based assays are now widely accepted for immunogenicity assessment and also make their

way into PK assessment. They potentially have lower background and less matrix interferences than traditional enzyme-linked immunosorbent assays (ELISAs). Gyrolab also has potentially lower matrix interference, while in addition, it is fully automated to reduce the need for extensive operator training. Furthermore, mass-spectrometry-based methods have undergone significant improvement in the recent years. Although no clinical application of mass spectrometry to clinical biopharmaceutical PK/PD (pharmacodynamic) analysis has yet been published, numerous feasibility studies indicate a potential future direction of the field.

Caution should be applied when comparing or extrapolating immunoassays on the basis of different formats or technologies. As they will give different results, a thorough understanding of the bioanalytical background is necessary. Bioassays focus on a functional drug, while mass-spectrometry-based assays only measure a short signature peptide. Antibody therapeutics, for example, can be measured as free, total, or partially target-engaged drug and possibly a combination thereof. The assay itself might influence the balance of these forms as well. Soluble targets are particularly challenging since their serum levels are fluctuating and they remain a part of the sample matrix in the assay.

Toxicology and clinical applications require thorough method validation. So far, no FDA guidance specific to large molecules has been published. However, the general bioanalytical guidance in combination with a series of white papers should be applied to LBAs. Many immunoassay validation parameters are similar to mass spectrometry. Some key differences include the appreciation of less accuracy and greater variability, as well as the need for more extensive selectivity testing. Applicable clinical patient matrices should be kept in mind rather than an exclusive focus on a healthy population during validation. Also, reagent lot qualification and bridging is essential in maintaining a bioanalytical.

PK and immunogenicity of biopharmaceuticals are assessed using LBAs. PK assay formats are dictated by scientific requirements as well as compound biology and program phase. “Generic” human IgG assays relying solely on commercial reagents may be deployed during a basic research stage, while drug-specific assays may be needed for toxicology and clinical applications. Immunogenicity screening assays, on the other hand, typically use a common bridge format with labeled drug, although confirmation assays can display a greater variety.

Despite or because of its age and low technology, immunoassays in their vast variety continue to shape the development of modern biotherapeutics into the foreseeable future. During recent years, advances in mass spectrometry and recombinant technologies demonstrated the feasibility for these methods to replace immunoassays in the long run. However, more method development work and general scientific acceptance are needed. Until then, LBAs will be inseparable from biopharmaceutical development.

14.2 INTRODUCTION—NEW LIGHT THROUGH OLD WINDOWS

During the last three decades, the advances in molecular biology, immunology, and protein biochemistry have led to the rise of a new class of drugs, namely, biopharmaceuticals, often referred to as *biologics* [1]. While traditional pharmaceuticals are of low molecular weight (100–500 Da) and chemically synthesized, biopharmaceuticals are high molecular weight proteins or peptides that are produced in living cells. Owing

to their structural complexity and size, these molecules cannot be readily analyzed by mass spectrometry methods. Up to now, immunoassays have been the method of choice to study the PK and immunogenicity of biopharmaceuticals.

The application of immunoassays to peptide bioanalysis has a long history that goes back to the first uses of animal-derived insulin [2]. Yalow and Berson [3] developed a competitive insulin radioimmunoassay (RIA) method in the 1960s, which was awarded the Nobel Prize in 1977. Their breakthrough demonstrated the feasibility of endogenous hormone quantification at very low concentrations [4]. The first immunoassays used polyclonal antibodies purified from human or animal serum, resulting in limited assay flexibility and reagent availability [2,3]. The monoclonal antibody technology developed by Köhler and Milstein [5] (Nobel prize in 1984) enabled the generation of highly specific, custom-made antibodies with virtually unlimited supply. As a result, antibody use proliferated in research and diagnostics immunoassays, as well as in development as therapeutic agents.

PK measurements of biopharmaceuticals rely on LBAs with high sensitivity and specificity. Antibodies specific to the drug enable quantification down to pg/mL levels in crude serum or other matrices without prior enrichment, thereby potentially reducing technical artifacts. Despite some limitations that are discussed in the following chapters, LBAs still enjoy widespread scientific and regulatory acceptance. Potential future trends including coupling to liquid chromatography-mass spectrometry (LC-MS) will be discussed.

A schematic applicable to most immunoassays is depicted in Fig. 14.1. Although competitive RIAs were the first format developed (Section 14.3.1), today dual-detection assays are the most common. They employ either two antibodies for capture and detection or a biological target in combination with a detection antibody [6]. As there are numerous variations on these themes, we have not discussed all possible scenarios. A common feature of all immunoassays is the need for a detection label. Initially, radiolabels were used allowing for unparalleled sensitivity. Later, enzymes such as horseradish peroxidase replaced the radiolabels [7–9], and most recently, acridinium, ruthenium, and lanthanide labels became available [10,11]. Further details on these methods are discussed later.

14.3 FROM HISTORY TO FUTURE—TECHNOLOGIES

As outlined above, a variety of LBA formats have been developed. Beyond their obvious differences, they share the same principle: an analyte-specific capture (antibody, target, or complementary peptide) is used to immobilize the drug of interest from a solution (matrix); for drug metabolism studies, typically plasma/serum or similar biological fluids are used as applicable. The immobilized drug is then detected with a second labeled analyte-specific reagent, which is either the labeled drug itself or, more often, another antibody. Depending on the assay format, wash steps are used to remove unbound substances.

Since biological matrices are not purified before application in the assay, the selection of appropriate reagents is key to method performance [12,13]. In particular, capture reagents must specifically recognize the analyte of interest among many endogenous proteins. Especially, closely related proteins can cause nonspecific signals that cannot be distinguished from specific binding [14]. If wash steps are used to remove unbound

Figure 14.1 Schematic representation of ligand-binding assays. Format A: target-mediated capture with antibody detection. Format B: antibody-mediated capture and detection. Alternative reagents that can be used are listed for each step. The use of secondary anti-species antibodies or labeled streptavidin detection systems has been omitted. HRP, horseradish peroxidase; AP, alkaline phosphatase.

substances, detection can be less specific. For example, anti-species antibodies are often used to detect bound antibodies. When working with samples from the same species as the antibody of interest (e.g., when detecting human therapeutic antibodies in human serum), other antibodies in the serum sample may become nonspecifically immobilized and not completely wash away. The nonspecifically immobilized antibody will be detected and will result in higher background.

As a general rule, decreasing the background improves assay sensitivity if signal/background ratios increase. Close attention should be paid to reagent purity, as contaminating proteins can result in higher assay background or increased variability. Unpurified antisera often contain antibodies that can bind “nonspecifically” in the assay. As greater specificity and affinity for both capture and detection will result in superior assay sensitivity, immunoaffinity purification is recommended for polyclonal antibodies when high background is encountered. In addition, optimization of blocking and assay buffer composition can provide reduced background and improved signal to noise ratios.

The selection of antibodies is dependent on the method’s objectives. Polyclonal antibodies tend to offer high affinity and are less affected by slight changes in the analyte [15]. Monoclonal antibodies bind to the molecule only in a single epitope and may not bind if the epitope is altered. This can also be used as an advantage to measure full-length molecules with antibodies binding at either end (alternatively,

polyclonal antibodies generated against subunits of the analyte of interest could be used). Monoclonal antibodies can be produced without changes for decades, making them ideal for long-running methods. When analyzing antibody therapeutics, anti-idiotypic antibodies are often used for highest specificity and improved assay sensitivity [16,17]. These antibodies bind to the antigen-binding site of the therapeutic antibody of interest. The downside of using anti-idiotypic-specific antibodies and other custom antibodies is the long lead time for immunization and production.

Besides full-length, “natural” antibody reagents, numerous alternatives have been deployed for either capture or detection of analytes of interest. Advances in antibody engineering allowed for molecular design of recombinant antibodies and for phage display-derived antibodies [18,19]. Receptors have successfully been used in immunoassays, mostly for capture but sometimes also for detection [10]. Lately, aptamers have been tested in LBAs [20]. These short oligonucleotide or peptide sequences are generated to bind to a target molecule of interest similar to antibodies. They can be selected and produced relatively quickly, but their applications to the bioanalysis of therapeutics are very limited [21].

14.3.1 Radioimmunoassay (RIA)

Although immunoradiometric assays (IRMAs) employing sandwich formats have been developed [22–25], classical RIAs are competitive assays (Fig. 14.2) [26,27]. The analyte of interest is captured from biological fluids by a specific antibody. Radioactively (^{125}I) labeled analyte is added to compete with the unlabeled drug for binding to the capture antibody. The immune complexes are then precipitated, typically by the addition of protein A or anti-antibody-coated beads, although other methods such as ammonium sulfate precipitation have been used. After pelleting the immune complexes by centrifugation, excess liquid, including unbound tracer, can be removed and retained radioactivity can be measured in a scintillation counter. The amount of radioactivity is inversely proportional to the analyte concentration in the sample.

Nowadays, most RIAs have made way for nonradioactive methods described in the following paragraphs. However, they still have their place when high sensitivity is required, for example, to quantify peptides and hormones [28,29]. For historic reasons and in order to achieve greatest sensitivity, RIAs are still used for PK bioanalysis of insulin compounds such as glargine [30] and in clinical chemistry laboratories. Besides traditional RIAs, IRMAs employing two antibodies were published as well for bioanalysis of insulin and insulin analogs [23].

14.3.2 Enzyme Immunoassay (EIA)

Although the nomenclature is used interchangeably throughout the literature, EIAs (enzyme immunoassays) and ELISAs are slightly different: EIAs are a direct homogeneous format translation of RIAs into a nonradioactive setting. The radiolabel is replaced by an enzyme such as alkaline phosphatase or horseradish peroxidase, followed by a signal-producing chemical reaction (colorimetric, chemiluminescent, or fluorescent). ELISAs are heterogeneous with an immobilized capture phase (Fig. 14.2). After the analytes of interest are bound, the remaining sample is washed off and a second analyte-specific antibody is used for detection. The enzyme label can be conjugated directly to the detection antibody, to an anti-species antibody, or to streptavidin if a biotin label

Figure 14.2 Schematic comparison of RIA and ELISA methods with example calibration curves: RIAs are competition assays. A single analyte-specific reagent (antibody) is used to capture the compound of interest. Labeled compound at a fixed concentration is added to compete with the analyte. The immune complexes are precipitated, and radiation is quantified in the pellet. ELISAs use an immobilized capture phase. Analyte is captured from the sample and detected with a second, labeled reagent. Each step is separated by washes.

is used. There are numerous variations on this basic theme, which are beyond this chapter's limits. Even though the strict use of the name ELISA implies the use of an enzyme, alternative labels can be applied, including nonenzymatic fluorophores and chemophores. Often these are referred to as *ELISAs*, although the proper nomenclature is “fluorescent immunoassay” (FIA) and “chemiluminescent immunoassay” (CLIA), respectively.

ELISAs are the most common format for large-molecule PK applications [31], with wide acceptance by regulatory agencies. Its overall simplicity and flexibility with respect to labels and procedures allow implementation in virtually any laboratory environment. However, some shortcomings exist: signal development is dependent on enzyme kinetics that is influenced, among other factors, by temperature, mixing, and substrate feedback inhibition. These are partially compensated for by the use of calibrator curves included on each assay plate, but higher data variability still is higher than that of small-molecule mass spectrometry methods. Also, the dynamic range is

rather limited even with excellent reagents. Therefore, PK study samples often have to be extensively diluted to be measurable within the assay range, introducing additional potential for analytical error. Newer technologies circumvent some of these limitations and are discussed below.

14.3.3 Other Assays

A number of immunoassay-based technologies became available in recent years. These include the following techniques.

14.3.3.1 Electrochemiluminescence. Often abbreviated as “ECL” (not to be confused with the enzyme substrate), electrochemiluminescence was commercially developed by Igen and incorporated into Roche’s line of diagnostic immunochemistry analyzers. MSD made the technology more broadly available for research laboratories. The basic format is similar to ELISA. However, the enzyme is replaced with a ruthenium label that is used to generate light on application of electric current. Special plates are required to facilitate the electric charge. Advantages of MSD assays include lower background and larger dynamic range than ELISA, thus potentially allowing for improved assay sensitivity. Enzyme-related variability is reduced as well. Since the signal reaction takes place only at the immediate proximity of the electrode, homogenous assays often can be developed without the nonspecific background issues of conventional ELISA [32,33]. The major disadvantage is the limited commercial choice, as MSD is the only supplier. However, MSD-based assays have found widespread acceptance for immunogenicity assays and increasing applications for PK assays [34].

14.3.3.2 Gyrolab. The Gyrolab (Gyros AB, Sweden) nanoscale assay platform transferred a standard fluorescence-tag immunoassay into a compact disk (CD). The entire assay only requires 5–10 μ L of sample or reagents and is fully automated. Briefly, biotinylated capture molecules are immobilized in flow-through streptavidin columns, followed by sample and a fluorophore-labeled detection antibody. Each column corresponds to a well in traditional plate-based assays. The run time per CD is ~50–60 min, but shorter runs can be accomplished using partial CDs. Advantages and disadvantages are similar to MSD assays. The small sample and reagent volume requirements as well as the automation are additional benefits of Gyrolab. We have used Gyrolab-based assays extensively in the lead identification and optimization space for PK measurements for over 14 drug discovery programs. The small sample volumes allowed for serial bleeds from transgenic mice, which are often too costly and limited to use in terminal bleed PK studies. Optimization of assay conditions was routinely finished within one to two days, and troubleshooting of any issues could be carried out with multiple runs in a single day.

14.3.3.3 Biacore. Surface plasmon resonance (SPR) is coming of age to study molecule interactions. Capture molecules are immobilized on a chip that allows detection of subsequent binding events individually through SPR effects. Wash steps are limited, and no labels are necessary. Biacore is routinely used to screen and characterize antibody reagents but has not found widespread acceptance for routine sample analysis because of limited throughput, high costs, and complex technology. Inherent

to SPR technology is limited sensitivity, particularly when studying high affinity interactions. Recently, Biacore became an important tool for immunogenicity assessment of large molecules, as it can detect low affinity anti-drug IgM that are washed away in traditional ELISA and sometimes even MSD (Section 14.7.2) [35,36].

14.3.3.4 Immuno Polymerase Chain Reaction (Immuno-PCR). This combination of traditional immunoassay and molecular biology attempts to harvest advantages from both worlds: protein-based detection and high sensitivity [37,38]. In this case, the detection antibody is labeled with an oligonucleotide that can be amplified via PCR. The immunosandwich capturing the analyte of interest is assembled following a standard immunoassay protocol. However, visualization and quantitation are accomplished by a subsequent PCR amplification of the oligonucleotide label. A number of variations have been developed on this theme, including commercial technologies [37]. Assay sensitivity, low background, and a large dynamic range are obvious advantages of immuno-PCR. On the other hand, the assay process is still rather complex and requires well-trained staff. Automated technologies are being developed to make daily applications more feasible. While there are a number of diagnostic applications, only a few PK assays are based on immuno-PCR [39].

14.3.4 Homogenous Assays

The adsorption of proteins to solid surfaces changes their tertiary and quaternary structures, potentially affecting interactions with other molecules in the assay [40]. Cancer antigen EpCAM II, for example, contains a discontinuous immunogenic epitope that is disrupted when coating the antigen directly onto microtiter plates (Verch unpublished data). Other limitations of solid-phase assays include wash steps and lengthy incubation times, making complete automation difficult. Some traditional plate-based technologies are amendable to semihomogenous formats, in particular, MSD assays or bead (flow) systems such as Luminex. Most homogenous assays, however, are performed entirely in solution in a single step without any washes. Different technologies are based on similar principles. Capture and detection molecules are labeled with complementary donor and receptor tags. On formation of the immunosandwich, energy transfers between the tags results in the generation of light or fluorescence (Fig. 14.1). Several technologies have been developed to optimize the light generation, including fluorescence resonance energy transfer (FRET), homogeneous time-resolved fluorescence (HTRF) [41], and, lately, AlphaLISA [42]. The close proximity necessary to achieve the energy transfer made widespread FRET and HTRF applications difficult, while AlphaLISA allows more flexible and larger immunosandwiches. The signal is based on chemiluminescence, which results from a cascade of several dyes [43]. Although there have been limited publications on AlphaLISA in the PK field, the technology is closely watched for its promising potential.

14.3.5 LC-MS for Proteins

Owing to their large size, proteins cannot readily analyzed by LC-MS-based methods. Large amounts of other proteins such as albumin that are present in preclinical and clinical matrices and often have high homology to the drug add to the bioanalytical complexity. However, LC-MS methods have evolved to potentially address some of

the disadvantages of ELISA [44,45]. Table 14.1 compares immunoassays to mass spectrometry methods. As a key difference, immunoassays can potentially measure entire functional molecules, while LC-MS focuses on peptide signatures after tryptic digests. If selected appropriately, these peptide signatures are unique to the analyte of interest in contrast to signals in immunoassays in which nonspecific and specific binding events are indistinguishable. While the selection of representative peptides out of a digest pool (billions of possible antibody sequences in a patient population) can be a challenge,

TABLE 14.1 Comparison of Immunoassay and Mass Spectrometry

Parameter	Immunoassay	LC-MS	Comments
Sensitivity	pg/mL range	μg/mL range	High affinity antibody reagent can improve sensitivity for both methods
Specificity	Limited (reagent dependent)	High (inherent)	—
Measured molecule identification	No	Yes	—
Accuracy/precision	Low (<20% bias and CV)	High (<10–15% bias and CV)	Both methods often perform well above expectations in the hands of experienced operators
Throughput	High	Medium to low	—
Cost/sample	Low	High	—
Assay development time	3–6 wk + 6–8 mo reagent lead	2 wk (no reagent lead unless immunocapture is used)	—
Special reagents required	Yes (specific antibodies and target)	No (except for immunocapture methods)	—
Complex sample matrix compatible	Yes	No (extraction necessary)	—
Matrix interferences	Yes	Potentially reduced	—
Internal standards required	No	Yes	Labeled standards for large molecules can be technically challenging
Free/total compound measurements (typical)	Mixture of free and total most common	Total	Method modifications can accommodate different types of measurements
Regulatory and industry acceptance	Reference method for large molecules	Reference method for small molecules	—

Abbreviations: LC-MS, liquid chromatography-mass spectrometry; CV, coefficient of variance.

in silico prediction has greatly reduced the efforts [46]. Chromatographic resolution and sensitivity are greater issues since a certain mass is necessary for detection. Combination methods of immunoaffinity analyte enrichment and LC-MS or MS-MS detection can address these disadvantages [47,48]. However, this also eliminates some of the advantages of LC-MS, that is, reduced development times and the lack of need for method-specific reagents.

A few assays have been published that apply LC-MS to PK of protein therapeutics [44,49,50], but clinical applications have lagged behind to date. Future improvements of the technology are undoubtedly still to come.

14.4 KINETIC CONSIDERATIONS IN LBAs

Immunoassays are influenced by affinities and kinetics between the different reagents and the matrix components. Binding reactions are reversible and limited by the equilibrium concentrations [51], making the application of kinetic models difficult with many unknown parameters (e.g., how much antibody/target has been immobilized in the capture phase) [52]. Affinity determinations made in buffer are not necessarily transferable to a serum matrix. Therefore, underlying principles between binding and release should be kept in mind for LBA development and data interpretation. The assay protocol is a key to understanding the data generated.

Although the distinction between bound and unbound drug is more applicable to small molecules, discussions evolved during the last few years, in particular, for antibody drugs. The so-called free antibody has at least one site available for antigen binding, whereas the “total” drug includes both forms with and without bound antigen [53]. Although some assay formats are claimed to measure free or total antibody, an LBA inevitably will have a mixture of both forms. The assay reagents used for capture and detection as well as the incubation times and conditions influence the equilibrium between free and total drug that may exist in the original samples. Despite these difficulties, some assumptions can be used to guide PK analysis: if the target is used for capture, mostly free antibody will be measured. Indirect capture systems (Section 14.5.2) or general anti-IgG assays are more likely to measure total antibody (Fig. 14.3). Owing to the complexity of the assay interactions, these assumptions should be treated with caution.

14.5 ASSAY FORMATS FOR LBAs

Immunoassays are very flexible and offer the possibility of numerous formats [10]. We have reviewed only a selected few that appear to be common and are of specific interest. Some general points should be considered for any immunoassay. Depending on the question, different assay formats may lead to different conclusions. There are also technical considerations of methods details that often are not widely appreciated. As discussed in Section 14.5.3, the sample matrix is not readily exchangeable: even seemingly small differences such as EDTA plasma versus heparin plasma or one rat strain versus an alternative strain can significantly change assay performance.

The use of commercial kits to analyze proprietary biopharmaceuticals is not always straightforward either. At minimum, the assay calibrators and quality controls (QCs)

Figure 14.3 Comparison of free versus total antibody immunoassays: Free antibody assays typically use the target or anti-idiotypic antibodies for capture. If target is bound to the antibody analyte, binding sites will not be available for binding in the assay. Total antibody assays capture and detect the antibody analyte independently from target engagement. Different populations of free, partially target-engaged, and bound antibodies are present depending on the ratios of target to drug (i.e., antibody analyte).

will need to be changed to reflect the new analyte. Typically, additional optimization for the new analyte is required, although options are limited due to the kit's preset reagent titrations. When using *in vitro* diagnostics (IVDs), some manufacturers may ask for a written assurance that data are not used to make patient treatment decisions outside the IVD label.

Assay sensitivity is tightly linked to reagents. Although assay platforms (Section 14.3) have an influence, sensitivity gains usually are modest if the reagents are not optimized. A switch from anti-species-specific to anti-idiotypic-specific detection can result in up to 100-fold greater sensitivity. More details are discussed in the following sections.

In the following sections, we present more details of assay formats. Since many biopharmaceuticals under development are antibody based, we focus on these to a greater extent. However, with some extrapolation, many of the lessons may be transferable to other analytes of interest.

14.5.1 Direct Assays

Formats that capture the analyte of interest directly out of the matrix are the most common applications. Typically, the target is immobilized on the solid phase and an

anti-species antibody may be used for detection. In the case of antibody compounds, a bridge assay may be employed, with immobilized target for capture and labeled target for detection. Many assays for biopharmaceuticals employ compound-specific custom reagents, in particular, anti-idiotypic-specific antibodies against antibody therapeutics. The key to a successful method is a combination of a suitable format and the quality of the reagents. Specificity and selectivity make or break LBAs.

Using anti-species antibodies can be problematic when operating with a similar matrix (anti-human antibodies and a human serum sample). Other endogenous antibodies beyond the therapeutic are present in 1000-fold excess so that even 1% nonspecific binding can result in significant background noise. These problems are reduced when clinical antibodies are tested in preclinical species. If cross-reactivity is limited, the so-called generic anti-human antibody assays can be conducted, and they have been published [54]. Anti-human antibodies are used for capture and detection to support various animal studies.

14.5.2 Soluble Target Assays

Soluble targets represent a specific challenge: at low drug-target ratios, very few binding sites of the drug may be available to engage immobilized target in the immunoassay, whereas at high drug-target ratios the reverse effect can be observed (Fig. 14.3). These effects can impact the measured PK profile depending on the assay format. Assays measuring Remicade, for example, were reported to exhibit TNF- α interference [55]. Other soluble targets that are subject to antibody therapy include various interleukins, Dickkopf-related protein 1, and proprotein convertase subtilisin/kexin type 9. Soluble ligands may also arise from shedding of membrane-associated molecules such as in the case of CD20 [56] and erb2/Her2 [57].

It may be necessary to evaluate whether the assay measures free or total compound and evaluation in two assays may help to establish the PK picture. Different approaches may be used to develop a total compound immunoassay with minimal soluble target interference.

An indirect capture assay to address potential interference of shed Her2/neu receptor in a Herceptin PK assay has been reported [58]. As the plate is coated with a mixture of target-engaged and free anti-receptor antibody, both compound forms (bound and free) can theoretically be captured in the assay. Dissociation steps, for example, with acid, are not commonly used for PK assays but could be applied to resolve anti-drug antibody interference and soluble target interference [54,59–62]. Very high affinity anti-idiotypic-specific antibodies can potentially elevate target interference as well, if they can outcompete the target engagement.

Recently, Doucet and Avrameas [63] used enzymatic digestion to degrade interfering targets. Through careful optimization of pepsin digestion conditions, they were able to digest soluble target in samples while retaining the activity of the antibody of interest.

14.5.3 Selectivity Issues

As LBAs provide only an indirect measurement via the assessment of a reporter signal, assay selectivity is essential and numerous articles have been published on that subject. Particularly, diagnostic biomarkers are scrutinized as patient decisions are made on the basis of assay results. Without selectivity and specificity, it is not possible to

determine whether a positive assay signal is actually related to the compound rather than nonspecific binding [64,65]. While it is acceptable to use normal, pooled matrix for calibrators and QCs, selectivity validation (also known as *spike recovery*) should be undertaken with the expected clinical patient population in addition to a normal population. Commercial, diagnostic patient matrices as close to the final population as reasonable can be spiked with the compound and tested as surrogate samples in the assay. Since selectivity issues can occur in unspiked and spiked samples, both require evaluation [66,67]. In particular, samples from patients with underlying autoimmune diseases can be challenging. Human-anti-mouse antibody (HAMA) or human-anti-rabbit antibody (HARA) can potentially bind to assay reagents and result in a false signal. Additives such as heterophilic blocking reagents or animal serum in the assay diluent may address potential selectivity issues [68,69].

14.5.4 Design of Experiments (DOE)

Immunoassays are a classic example of a multifactorial system where different factors influence each other in generating the final result [70]. Traditionally, assays were developed “one factor at a time,” that is, first optimal coating, then blocking, then detection, and so on. Since each condition is dependent on the others, checkerboard systems were applied to optimized coating and detection in conjunction.

The Quality by Design (QbD) initiative from the FDA aims at improving pharmaceutical manufacturing processes [71] using design of experiments (DOE) as a central component for optimization. Although not commonly applied yet, DOE is gaining more attention in the development of various types of immunoassays [72,73]. It can be used at three stages: (i) development (screening of factors and influences), (ii) optimization, and (iii) method robustness [74,75]. While a similar result may be achieved by applying good scientific rationale and experience, DOE can speed up the development of complicated assays and better define the design space of any method. This can be advantageous when accommodating changes (reagents, equipment, environment) or when outsourcing methods in later stages of development to other laboratories. Although DOE can help significantly in assay development and the control of critical factors, it does not replace critical scientific evaluation. Experimental conditions and results need to be analyzed not only from a statistical but also, most importantly, from a scientific perspective. Mathematical models cannot replace biological understanding of what is going on in the assay.

14.6 IMMUNOASSAY VALIDATION

14.6.1 Guidelines, White Papers, and Industry Standards

The application of immunoassays in the safety assessment and clinical development space requires validation to FDA and ICH (International Conference on Harmonization) standards. The chapter titled *Analytical Method Development and Validation in Accordance to the Regulatory Guidelines* of this encyclopedia focuses on this subject in more detail, while below, we present a few basic concepts as they apply to immunoassays. Existing FDA industry guidance is mostly applicable to LC-MS methods, and only limited sections apply to immunoassays [66,76]. A series of white

papers coming out of industry–FDA workshops have been published to help with setting up suitable validation plans [67,77–79], and some key validation parameters are listed in Table 14.2. Generally, LBAs are associated with greater variability and lower accuracy compared to LC-MS methods. Prevalidation experiments including different reagent lots, if available, may avoid surprises during a critical time line.

Ruggedness is an important aspect of validation since the method might have to be transferred to other laboratories [80]. Incubation times, temperatures, and equipment minimally should be evaluated. For assays carried out on the laboratory bench, a room temperature range should be tested. Caution should be applied to changes in the laboratory environment between summer and winter, as humidity and temperature can shift drastically. Ideally, temperature-controlled incubators are used. Some assays may even be sensitive to regular fluctuations from room air handlers, for example, if low affinity IgM antibodies are used whose binding can be influenced by subtle changes.

Once the method is deployed for study support, incurred sample reanalysis (ISR) is a regulatory requirement [81]. Selected samples are reanalyzed and compared to their original test value. The two results should be within a certain acceptance range: typically at least 66% of the retests should be within 30–40% of the original test value.

14.6.2 Best Practices and Common Pitfalls

The complexity of immunoassays can result in seemingly limited method changes having major effects with—in extreme cases—the method falling apart. Thus, extensive method validation, as described earlier, is a prerequisite to generating solid data.

As reagents are essential for immunoassay performance, lot switches should be avoided or minimized. Any new critical reagent lot, for example, capture and detection reagents, needs to be qualified for assay performance at least with accuracy and precision evaluation. Obviously, the uniqueness of immunoassay reagents prohibits the use of “equivalent” reagents; for example, replacement of an anti-species detection antibody from one supplier with an antibody from a different source. Calibrators and QCs should be bridged to previous lots and trending in preparations should be monitored.

As immunoassays can exhibit significant matrix effects, calibrators and QCs should be prepared in a matrix that is reflective of the samples. Attention needs to be paid to details: for example, plasma comes in different varieties (EDTA, Heparin, LiCl) that are not interchangeable. At minimum, the QCs need to simulate actual samples appropriately even if calibrators are prepared in buffer. It is preferable to have both calibrators and QCs prepared in the appropriate matrix.

Large molecules can also display a nonparallelism phenomenon. In this case, study samples, but not necessarily *ex vivo* spiked samples, do not dilute parallel to the calibrator curve [82]. Thus, the calculated sample concentrations differ depending on what dilution is used and multiple dilutions are necessary for each sample.

14.7 APPLICATIONS

It is important to keep the bioanalytical background of each method in mind. Mass spectrometry methods, LBAs, or cell-based bioassays each measure different aspects of a molecule and, thus, will seldom result in comparable data when applied to the same sample [83,84]. While mass spectrometry focuses on purified, small fragments

TABLE 14.2 Validation Parameters for Immunoassays and Expected Performance as Outlined in White Papers^a

Validation Parameter	Expected Assay Performance	Comments
<i>Pharmacokinetic Assays</i>		
Accuracy and precision	20% Bias/CV 25% Bias/CV at the LLOQ	Higher bias/CV acceptance criteria need to be justified with performance data
Dilution linearity	Linear over the applicable sample dilution range	—
Hook (prozone) effect	None	If a hook effect is observed, samples need to be tested at different dilutions
Specificity	No cross-reactivity with other sample components	—
Selectivity	Unspiked: BLOQ Spiked: 20% bias to nominal concentration	—
Robustness	Incubation ranges (time, temperature) do not affect assay	—
Stability, freeze–thaw	20% Bias/CV ^b compared to fresh (unfrozen) baseline	—
Stability, sample handling	20% Bias/CV ^b compared to baseline	Test conditions should cover sample processing during the assay
Stability, sample storage (long term)	20% Bias/CV ^c compared to baseline or nominal	Time should cover the storage time of the samples and beyond for retest options
Stability, reagents	No effects on assay performance as tested by accuracy and precision	—
<i>Immunogenicity Assays</i>		
Accuracy and precision	CV: <20%	High variability affects the normal cutoff
Negative sample cutoff	5% False-positive rate	False positives are used to demonstrate the method that can detect bridging
Positive control sensitivity	Preclinical: 1 µg/mL Clinical: 250–500 µg/mL	—

(continued overleaf)

TABLE 14.2 *(continued)*

Validation Parameter	Expected Assay Performance	Comments
Drug interference	No interference with the expected drug concentrations at the sampling time point	Immunogenicity samples should be taken when little or no drug is on board
Robustness	Loss of sensitivity of samples spiked with positive control ^c : <20% bias	—
Stability, freeze–thaw	Loss of sensitivity of samples spiked with positive control ^c : <20% bias	—
Stability, sample handling	Loss of sensitivity of samples spiked with positive control ^c : <20% bias	—
Stability, sample storage	Loss of sensitivity of samples spiked with positive control ^c : <20% bias	—
Stability, reagents	No effects on assay performance as tested by accuracy and precision	—

Abbreviation: CV, coefficient of variance; LLOQ, lower limit of quantification; BLOQ, below the LLOQ.

^bAlternative: bias/CV within the method acceptance criteria for accuracy/precision.

^cActual positive samples may be used if available.

of large-molecule digests, bioassays measure functional aspects that often require a complete protein. Depending on the assay format, LBAs might measure subparts or complete and functional analytes.

Different immunoassay formats do not necessarily give similar results [84,85]. The PK parameters of gentamicin derived from RIA and ELISA displayed significant differences in distribution volume, clearance, and half-life despite good bioanalytical correlation [86]. Similar issues were encountered for a PK rituximab assay [87]. Therefore, a thorough understanding of bioanalytical assay background is essential to analyze PK data for large molecules [88].

Interestingly, to characterize abnormal PK bioanalytical data caused by anti-drug antibody responses interfering with LBAs, another immunoassay is used to assess immunogenicity.

14.7.1 Pharmacokinetics

Most if not all biotherapeutics that are marketed established label PK parameters by immunoassay, although the assays rarely are published in detail [31]. Their applications stretch through the drug development process from lead optimization of optimal PK factors, over toxicology studies to assess the compound's safety profile to determination of final PK for the drug label. Basic information derived from bioanalytical immunoassay data includes area under the curve, half-life, and maximum and trough concentrations, while more complex modeling allows for human dose prediction.

As assay development can be time consuming and format switches can lead to changes in measurements, a suitable PK strategy should be considered early enough to avoid spending resources on molecules that will not see the development space. Well-designed and characterized LBAs can sometimes replace *in vivo* studies for early compound screening. Binding of antibodies to the neonatal Fc-receptor (FcRn) can be assessed *in vitro* in a preliminary fashion [89]. Ideally, the assay format remains the same from discovery to clinical so that bioanalytical data can be easily compared. As this is not realistic under a drug development paradigm, a staged approach can be pursued: a basic assay with minimal qualification can be established with commercial reagents initially to carry the molecule through discovery and candidate selection. Limited toxicology studies potentially could still be supported by an early format if it will be validated. In the case of antibody therapeutics, a "generic" anti-human IgG assay sometimes is used throughout the preclinical space [54,90]. Clinical assays, on the other hand, often require compound-specific assays for regulatory compliance, and the assay should be set up more robustly with tight control over assay reagents. Typical development points where bioanalytical assays can be easily switched are before toxicology and clinical programs. Whenever format changes are involved, extrapolations of PK data should be approached, with close consideration of the bioanalytical background.

Since preclinical studies including toxicology are limited in scope and time frame, novel assay technologies can easily be implemented. On the other hand, clinical studies can last for years and often are outsourced as a commodity. Therefore, clinical assay development needs to take equipment and capabilities of contract research organizations (CROs) into consideration. In addition, clinical assays need to be robust enough to withstand reagent lot, operator, laboratory site, and other changes. If necessary, a qualification strategy should be put in place to address these issues. Abbreviated

accuracy and precision evaluations typically are used. To avoid a need for assay redevelopment and bridging in the middle of a clinical program, novel technologies with limited vendor and CRO support should be avoided.

14.7.2 Immunogenicity

Assessment of anti-drug immune responses is gaining increased attention driven to a large extent by the development of anti-erythropoietin- α antibodies in patients receiving recombinant erythropoietin products. Between 1998 and 2000, ~ 13 patients with pure red cell aplasia were reported in France compared to 3 cases in the previous 10 years, ultimately accumulating to 191 cases throughout Europe [91]. This sharp increase was linked to anti-drug antibodies (ADAs) against recombinant erythropoietin α therapy leading to an autoimmune reaction against the patients' endogenous protein. The investigation of the case displayed well how different immunoassay formats and technologies can monitor various aspects of an issue. Initial radioimmunoprecipitation assays and ELISAs were able to detect high affinity IgG only. Later investigations with Biacore revealed the presence of temporary IgM against erythropoietin α [36,92]. These low affinity interactions had been overlooked as the stringent conditions required for ELISA/RIA-washed IgM out before detection. The elimination of secondary detection antibodies also made detection of subclasses other than IgG more feasible.

Bridge immunoassays using labeled drug are a standard format to screen sera for potential, with various technologies being deployed. RIAs and ELISAs are widely spread, but in recent years, MSD-based assays have been favored, as they allow for greater sensitivity [93]. They combine plate-based assay advantages such as high throughput and limited costs with Biacore/SPR advantages including the detection of low affinity IgM antibodies [94].

Immunogenicity assessment should not be based on a single assay, but it requires a more comprehensive strategy [95–98]. The initial screening assays take the variability of an undosed patient population into account to statistically set up a false-positive rate at 5%. This serves as a demonstration that the assay can recognize potential immune responses against the drug among a high background of nonresponders. Since factors other than specific ADA has the potential to form a bridge in the screening assay, caution should be applied when interpreting potential positive results [60]. Confirmation assays are necessary, which often include immunoprecipitation and/or titration of the response. Only a positive signal in screening and confirmation assays can be acknowledged as true ADA in order to be characterized further, for example, through isotyping or evaluation of neutralizing ADA activity. In recent years, replacement of cell-based functional assays by LBAs has been discussed. Although used occasionally, regulatory agencies are not quite convinced by this approach.

During drug development, PK and ADA analyses go hand in hand. A sudden decline of drug concentrations in serum beyond the molecule's expected PK is a good indicator of ADA interfering with PK measurements. Since animal immunogenicity is not predictive of human immunogenicity, the PK profile may be sufficient during early compound development. Toxicology studies eventually will require at least a screening assay to identify potential ADA-positive sera. Clinical immunogenicity assessment is a multilayered approach consisting of a screening assay, a confirmatory assay, and characterization assays. The immunogenicity assay strategy will closely define the patient's immune responses that can be detected [98,99].

14.7.3 Pharmacodynamics

While PK and ADA analyze the effects of the body onto the drug, PD measures the effects of the drug on the body. Biomarkers are increasingly used to assess biotherapeutics efficacy and have become a focus of regulatory agencies throughout the world [100]. The chapter titled *Bioactivation and Reactive Metabolite Assays* of this encyclopedia discusses the subject in more detail. Here, we focus on some bioanalytical examples where immunoassays play a role again.

Three basic assay categories can be distinguished: (i) standard clinical chemistry such as cholesterol and blood protein assessment; (ii) target monitoring, for example, the Her2/neu assays for Herceptin treatment; and (iii) complex multiplex assays monitoring marker panels, for example, for cancer risk prediction (Fig. 14.4).

14.7.3.1 Clinical Chemistry Assays. Changes in blood proteins often are useful biomarkers that do not require extensive assay development. Diagnostic assays are available for most serum components and routinely deployed in clinical reference laboratories using automated immunoanalyzers. These machines can analyze hundreds of patient samples per hour from beginning to end, requiring only sample and reagent loading by the operator. The assay principles are the same as discussed earlier, with an immunosandwich being assembled on a bead surface followed by detection with a label. However, assays specific for drug development often are difficult to establish due to the closed platform design of immunoanalyzers.

14.7.3.2 Target Monitoring. Biotherapeutics typically have a well-defined target pharmacology that can be used to develop biomarkers or companion diagnostics.

Figure 14.4 Schematic overview of (a) general, (b) stratified, and (c) personalized medicine. Immunoassays measuring standard blood chemistry and components typically are high throughput, automated assays that can be applied to the general population. Assays measuring drug targets can be either manual or automated and are used to identify patient subsets with specific features, for example, potential responders to therapy. Personalized medicine assays tend to be complex and carried out manually to date. Results are different for each person in the ideal case.

Herceptin is a good example for biomarker and assay development. This therapeutic antibody is used to treat Her2/neu-receptor-positive breast cancer [101]. Starting in early clinical trials and all the way to marketing of the drug, the target has been used to select patients who can benefit from the drug [102]. Initially, an immunohistochemistry assay and a fluorescence *in situ* hybridization (FISH) assay were available for patient selection. Recently, ELISAs measuring serum Her2/neu concentrations have become available. It is important to note that the different assay types also differ in their claims: patient selection for drug therapy can be based on FISH and immunohistochemistry results, as these are FDA-approved companion diagnostics [103]. ELISA measures a different aspect of the target pharmacology and is only cleared for cancer monitoring. Similar to the discussion of PK assay formats, Her2/neu biomarker assays are not interchangeable.

14.7.3.3 Multiplex Analysis. The trend to personalized medicine requires more extensive biomarker analysis. Instead of single target measurements, panels of multiple markers are combined to diagnose or predict disease. Most of the research focuses on pharmacogenomics, but some protein panels are being developed as well. When dealing with a small number of protein biomarkers, individual immunoassays can be carried out. But complex panels may be too costly and cumbersome for single assay analysis, and multiplex assays are more efficient. Going beyond single Her2/neu tests, the next generation of assays is on the horizon, combining multiple analytes to a single patient score [104]. The diagnosis of ovarian cancer also exemplifies the development from single biomarker tests over “oligoplex” to multiplex assays. Initially, CA125 serum concentrations were measured by RIA and ELISA to monitor cancer progression [105]. Recently, combinations with HE4 serum concentrations indicated a diagnostic benefit [106], and current trends indicate multiplex immunoassays on the horizon [107–109].

14.7.3.4 LBA Technologies for PD Assays. While some LBA technologies discussed previously can be modified for multiplex analysis, additional options are available to parallelly measure several analytes. MSD offers multiarray plates where up to nine different analytes are spot coated onto a single microtiter plate well. Signals from each spot can be analyzed individually.

Time-resolved ELISA and AlphaLISA can accommodate up to four multiple analytes by using different detection labels in the same assay. Thus, the analytes are only resolved by the detection side of the LBA but not at the capture as in MSD’s plates.

Bead-based arrays as offered by Luminex and its partners as well as by BD Biosciences have advanced into diagnostic applications already. The immunosandwich is assembled with capture reagents immobilized on dye-coded beads combined with a fluorescently labeled detection antibody. The dual signal of bound detection antibody together with each bead dye is measured individually in a flow-through system. Up to 100 analytes can be distinguished through the bead colors on Luminex systems. A number of other multiplex options are available, which are beyond the scope of this chapter [110,111]. The main obstacles for multiplex immunoassays are reagent selectivity and cross-reactivity, as well as potentially increased variability of multiplex test systems.

If patient treatment decisions and/or drug label claims are made based on biomarker analysis, thorough assay validation is required. While many parameters are similar to

PK assay validation (see above), more stringent standards are applied to diagnostic biomarkers as outlined in guidelines by the ICH [112,113].

Since a detailed discussion of PD markers and assays are beyond the scope of this, the above-listed examples represent only a very limited view of a vast and rapidly expanding field.

15.1 INTRODUCTION

In capillary electrophoresis (CE), mixtures of charged compounds migrate under the influence of an electric field in a capillary tube and are separated according to their differences in charge-to-size ratio. The capillary is typically made of fused silica with typical dimensions of internal diameter (i.d.) $<100\mu\text{m}$ (most commonly used are 50 and $75\mu\text{m}$ i.d.) and length smaller than 100 cm. The advantage of performing electrophoresis in capillary tubes is the effective dissipation of joules heating that is generated as a result of the application of the electric field. A number of key advantages of CE have been demonstrated over the past three decades, including very high resolving power due to high peak efficiency, fast analysis time, small sample size, feasibility and flexibility of manipulating chemical selectivity, broad scope of samples and applications, high throughput capabilities (especially with microfluidic platforms), and so on. There are four main CE-based techniques: capillary zone electrophoresis (CZE), capillary isotachopheresis (CITP), capillary isoelectrofocusing (CIEF), capillary gel electrophoresis (CGE), and electrokinetic chromatography (EKC). These methods differ with respect to migration and separation mechanisms and subsequently the scope of applications. Micellar electrokinetic chromatography (MEKC) is the only CE technique that is capable of separating uncharged and charged compounds [1–5].

Terabe *et al.* [6] extended the scope of CZE to separate uncharged molecules by incorporating charged micelles in the aqueous buffer solution. The technique, named MEKC, uses the same instrumental setup as CE. Charged organized media such as micelles are incorporated in the buffer solution and serve as the separation medium for uncharged solutes. The charged micelles serve as pseudostationary phases as they provide sites of interactions for solutes in the sample mixture (similar to stationary phases in chromatography). For the MEKC separation of uncharged solutes, the pseudostationary phase must be charged; thus, nonionic and zwitterionic surfactants can only be used in mixed micelles along with a charged surfactant.

Hydrophobic interaction plays a predominant role in solute partitioning into micelles and consequently retention in MEKC, while hydrogen-bonding and dipolar interactions contribute to selectivity. MEKC is very similar to reversed-phase liquid chromatography (RPLC) with regard to the scope of applications. This is due to highly similar underlying types of interactions that control retention and selectivity in both techniques. MEKC can be viewed as a hybrid of RPLC and CZE as the separation process incorporates hydrophobic and polar interactions, a partitioning mechanism, and electromigration. However, MEKC offers a combination of unique features of CZE and RPLC such as high efficiencies, rapid analysis, small sample size, small solvent consumption, and versatility of incorporating chemical selectivity in the separation process. It offers higher efficiency than RPLC and capillary electrochromatography (CEC). The number of theoretical plates in an MEKC separation can be 10 times or higher than that in RPLC. Another major advantage over conventional chromatographic techniques as well as CEC is the flexibility and ease of changing chemical composition of the pseudostationary phases. For example, the type and/or composition of the micellar solution can be easily modified or replaced by simply rinsing the capillary with a new type of pseudostationary phase. The equilibration times are often very rapid. This inherent flexibility of controlling key parameters leads to enhanced separations and greatly facilitates the process of method development. MEKC is mostly suited for analysis of small molecules and is the only CE technique that is capable of separation of both charged and uncharged compounds as well as structural, positional, and chiral isomers with applications in analysis of pharmaceutical, clinical, environmental, biological, and chemical samples [1–5].

15.2 MIGRATION PATTERNS AND RESOLUTION IN MEKC

15.2.1 Uncharged Solutes

Figure 15.1 illustrates the migration pattern and separation of two hypothetical uncharged solutes in MEKC using a fused silica capillary with negatively charged walls. The mixture is introduced at the anode inlet of the capillary and migrates with the electroosmotic flow (EOF) toward the cathode, where the detector is located. The negatively charged micelles migrate toward anode in the electric field at an electrophoretic mobility (μ_{mc}) that is proportional to their charge-to-size ratios. Anionic micelles migrate in the opposite direction of the EOF in an uncoated capillary. Typically, the EOF velocity is stronger than the electrophoretic velocity of anionic micelles under “normal” conditions (e.g., an uncoated capillary and pH > 6). As a result, the anionic micelles are carried toward the cathode. Using cationic micelles, the capillary wall is coated with the positively charged surfactants and often times it

Figure 15.1 Schematic diagram of migration of uncharged compounds in MEKC with anionic pseudostationary phases. Separation of solutes S1 and S2 is achieved due to their differential partitioning into the pseudostationary phase. The uncharged solutes are eluted within an elution window (t_{mc}/t_{eo}).

leads to a reversal in the direction of the EOF. It is therefore necessary to reverse the polarity of the electrodes in the CE setup to ensure the elution of the cationic micelles and consequently the uncharged solutes through the detection window.

The two uncharged compounds, S1 and S2, are separated due to differences in their water–micelle partition coefficients, K_{mw} . Charged micelles migrate in the electric field and elute at a certain time (t_{mc}). Subsequently, MEKC has a limited migration window between the elution time of an unretained solute, t_{eo} , and the migration time of micelles, t_{mc} (Figure 15.1). The elution window is defined by two types of solutes. First are the unretained solutes that do not interact with micelles ($K_{mw} \sim 0$) spend all of their migration times in the bulk aqueous phase and migrate at the electroosmotic mobility. These are typically uncharged polar molecules such as methanol or acetonitrile that are EOF markers and elute at t_{eo} . The other end is defined by the elution of analytes that interact so strongly with the micelles ($K_{mw} \sim \infty$) that they spend all of their migration time with micelles. The t_{mc} markers are typically very hydrophobic compounds that are sparingly soluble in the aqueous media, reported examples being Sudan III and dodecanophenone. The elution times for these analytes coincide with the micellar migration time, t_{mc} . The existence of an elution window limits the peak capacity in MEKC as all uncharged solutes are to be separated between the migration time of an unretained solute, t_{eo} , and a fully retained solute, t_{mc} . The size of the elution window varies with the type and concentration of the charged pseudophases, the presence of organic modifiers, mixed micelles, or capillary wall modification [1–5].

Like chromatography, retention factor in MEKC is defined as the ratio of the number of moles of solute in micellar pseudostationary phase, n_{mc} , and that in bulk aqueous phase, n_{aq} . Retention factor is directly proportional to the micelle–water partition coefficient, K_{mw} , and phase ratio, Φ as follows:

$$k = \frac{n_{mc}}{n_{aq}} = K_{mw} \Phi \quad (15.1)$$

Retention factor in MEKC can be determined from migration time data using the following equation:

$$k = \left\{ \frac{t_r - t_{eo}}{t_{eo} \left[1 - \left(\frac{t_r}{t_{mc}} \right) \right]} \right\} \quad (15.2)$$

This is very similar to the equation for retention factor in conventional chromatography with the exception of the additional term $(1 - t_r/t_{mc})$ in the denominator. This term indicates the existence of an elution window due to the fact that the “stationary phase in MEKC is actually mobile.” If t_{mc} approaches infinity (i.e., stationary micelles), the extra term in the denominator is omitted and the retention factor equation becomes the same as that in conventional chromatography.

15.2.2 Ionizable Solutes

In addition to partitioning into micelles and migrating at the micellar mobility, charged compounds possess electrophoretic mobilities of their own in the bulk aqueous solvent. As a result, the observed retention time also includes the time that solute migrated electrophoretically in the bulk aqueous phase. Migration patterns for ionizable solutes (weak acidic and basic compounds) are considerably more complicated than uncharged compounds in MEKC due to existence of acid–base and ion-pairing equilibria in the aqueous solution and [7–9]. For separation of ionizable solutes in MEKC, control of buffer pH (in addition to type and concentration of micelles) would be critical in method development and optimization of separation. Quantitative models have been developed that would allow prediction of migration patterns of ionizable solutes and subsequently rapid optimization of separation conditions based on limited initial experiments [9].

15.2.3 Resolution in MEKC

Equation 15.3 shows the resolution equation for uncharged solutes in MEKC:

$$R = \left(\frac{N^{1/2}}{4} \right) \left(\frac{\alpha - 1}{\alpha} \right) \left(\frac{k_2}{1 + k_2} \right) \left(\frac{1 - \left(\frac{t_{eo}}{t_{mc}} \right)}{1 + \left(\frac{t_{eo}}{t_{mc}} \right) k_1} \right) \quad (15.3)$$

As can be seen, Equation 15.3 has the same format as that for conventional chromatography as it indicates that resolution depends on three terms related to efficiency, selectivity, and retention [6]. The fourth term is unique to MEKC that represents the existence of an elution window.

Again, if micelles were truly stationary (i.e., $t_{mc} \sim \infty$), the fourth term would drop out and the equation would be identical to that in conventional chromatography. The size of the elution window has a significant impact on MEKC separations. Likewise, peak capacity, n , can also be increased with wider elution windows as follows:

$$n = 1 + \frac{\sqrt{N}}{4} \ln \frac{t_{mc}}{t_{eo}} \quad (15.4)$$

Like chromatography, better resolution is achieved at higher efficiency. The disadvantage of the limited elution window is mostly compensated by the large number of theoretical plates that are routinely achieved in MEKC. The concentration and type of surfactant (pseudostationary phase) should be optimized to enhance resolution due to their influence on at least three of the parameters (k , α , and t_{mc}/t_{eo}).

15.3 CONTROL AND PREDICTION OF RETENTION IN MEKC

The primary role of surfactant concentration is to adjust retention factor to within the optimum range in order to achieve better resolution. The relationship between retention factor, k , and surfactant concentration can be described as in the following equation [6]:

$$k = \frac{v(C_{\text{sf}} - \text{CMC})}{1 - v(C_{\text{sf}} - \text{CMC})} K_{\text{mw}} \quad (15.5)$$

where the first term is the phase ratio, ϕ , defined as the volume of the micellar pseudostationary phase over that of the bulk aqueous phase (i.e., $V_{\text{mc}}/V_{\text{aq}}$) and is related to v (surfactant molar volume), C_{sf} (total surfactant concentration), and critical micelle concentration (CMC). K_{mw} is the partition coefficient of a solute between an aqueous phase and micelles. In general, retention factor increases linearly with surfactant concentration, as Equation 15.5 can be simplified to, because the denominator approximately equals to one under typical operating surfactant concentrations as follows:

$$k = K_{\text{mw}}v(C_{\text{sf}} - \text{CMC}) \quad (15.6)$$

A unique advantage of MEKC is that the phase ratio can be determined accurately (first term in Eq. 15.5) and will not change from capillary to capillary or with time as is the case for chromatography columns. The phase ratio in MEKC is related to two intrinsic properties of the surfactant: partial specific molar volume (v) and CMC, as well as surfactant concentration. This provides a unique opportunity to predict retention factor in MEKC for solutes with known micelle–water partition coefficients without any prior experiments. Unfortunately, there is a lack of extensive and reliable K_{mw} databases.

Additivity-based approaches have been developed to calculate micelle–water partition coefficients from solute structure [10,11]. Micelle–water partition coefficients can be described as the sum of the partition coefficients of the constituent atomic/molecular fragments, measured by fragmental constant values, f_i , as well as correction factors to account for various “intramolecular effects” that cause deviations from the predicted partition coefficients as follows [10,11]:

$$\log K_{\text{mw}} = \sum_{i=1}^n a_i^* f_i + \sum_{i=1}^m k_i^* C_m \quad (15.7)$$

where f_i is the fragmental constant and a_i is the frequency of occurrence of each fragment found in the solute structure, k_i is a constant that varies with the type of “intramolecular effect.” This equation is based on the Rekker’s fragmental constant approach for calculation of octanol–water partition coefficients. The fragmental constants of 41 fragments in the sodium dodecylsulfate (SDS) micelle system have been determined. Using Equation 15.7, the SDS micelle–water partition coefficients and subsequently their retention factor, and retention times for 170 aromatic solutes were successfully predicted in MEKC using SDS micelles. The linear regression of the predicted versus observed retention times resulted in $R^2 = 0.971$ and slope of 0.992.

15.4 PSEUDOSTATIONARY PHASES IN MEKC

In addition to micelles made of synthetic surfactants above their CMCs [1–6], a wide variety of pseudostationary phases have been used that has significantly extended for the applications of the technique. Some examples of pseudostationary phases are ionic polymers [12] cyclodextrins (CDs) and other chiral reagents [13], fullerenes and carbon nanotubes (CNTs) [14], vesicles [15,16], liposomes [17–20], dendrimers, and others.

15.4.1 Micellar Pseudophases

Micelles have been the most commonly used pseudostationary phase in EKC. Anionic alkyl chain surfactants, especially SDS, have been the most widely used surfactant type. The popularity of SDS can be attributed to the high aqueous solubility, low CMC, low Kraft point, low UV molar absorptivity even at low wavelengths, availability, and cost. Serendipitously, SDS might provide the “right” type of selectivity for many solute mixtures. Anionic alkyl chain surfactants, especially SDS, have been used in a variety of applications such as MEKC separations of phenols and other acidic solutes, pharmaceutical amines, organic solvents, keto compounds and carbohydrate derivatives, fungicide and phytotoxin, caffeine metabolites in human urine, DNA adducts, pharmaceuticals such as antibiotics, vitamins, sulfonamides, xanthines, peptides and proteins, organometallic and ligands, amino acids, sulfur and nitro compounds in environmental applications, flavonoids in foods, and nucleic acids constituents in body fluids [1–5].

As an alternative to SDS, the use of bile salt surfactants in MEKC separations has become popular due to their different selectivities as compared to SDS. Bile salt surfactants have very different aggregation properties and structures from SDS micelles. They can tolerate relatively higher concentration of organic modifier (30% organic solvent) than SDS micelles without a disruption of their structural integrity. Bile salts have been used in a variety of MEKC separations such as steroids, amino acids, benzodiazepines, synthetic colors, bioactive compounds, environmental analysis, proteins and peptides, bilirubin, organic acids, and hydrophobic compounds, including polycyclic aromatic hydrocarbons, chiral and diastereoisomers, and anti-HIV agents [1–5].

The use of fluorinated surfactants in MEKC separations has been very limited. This has been mostly due to the lack of availability of MEKC compatible fluorocarbon surfactants in high purity. Ye *et al.* [21] reported the first application of the fluorocarbon micelles of lithium perfluorooctane sulfonate (LiPFOS) for the MEKC separations of a group of small peptides and reported very different selectivity and elution patterns as compared to SDS. LiPFOS micelles are stronger hydrogen-bond donor (HBD) than other micellar systems that have been studied thus far [22,23].

Cationic surfactants generally interact with the negatively charged silica capillary wall and reverse the direction of the EOF. As a result of the reversed EOF, the polarity of the electrodes would have to be reversed in order to elute solutes through the detector window [1–5]. Cetyltrimethylammonium bromide (CTAB) micelles are among the strongest hydrogen-bond acceptors (HBAs), thus have a very different interactive behavior than SDS or LiPFOS micelles [22,23]. The usefulness of cationic surfactants has been explored in a number of MEKC applications. A few examples are phenolic carboxylic acids, charged molecules with nearly identical electrophoretic mobilities such as bis(amidinohydrazones), nucleic acid constituents, cocaine and illicit drugs, adrenergic blocking agents, glycosylated compounds, and aromatic hydrocarbons [1–5].

Surfactants with a zero net charge such as nonionic and zwitterionic surfactants can be used along with an ionic surfactant as mixed micelles. In order to separate uncharged molecules in MEKC, charged surfactants must be used. They can also have a great influence on the MEKC separation of charged molecules. Both nonionic and zwitterionic surfactants have been used alone for the separations of charged compounds such as amino acids and polypeptides. Nonionic surfactants and mixtures of anionic/nonionic surfactants have been shown to provide different selectivities, reduced currents, and changes in elution window sizes as compared to anionic surfactant systems. Zwitterionic surfactants have been used alone and in conjunction with SDS in MEKC. Because these surfactants do not increase the conductivity of the buffer, they can be used at high concentrations, while still allowing the use of high voltages and large i.d. capillaries.

15.4.2 Polymeric and Nanoparticle Pseudostationary Phases

At least five different classes of polymeric phases have been reported, including polymer micelles where surfactant monomers are polymerized and covalently bonded together [12], cascade macromolecules such as starburst dendrimers, and ionic block copolymers [1–5], fullerenes, and nanoparticles [24,25]. Figure 15.2 illustrates the structures of some polymeric surfactants. Initially, polymeric pseudostationary phases (PSP) were used for the MEKC separation of highly hydrophobic compounds that would require use of relatively high concentrations of organic modifiers in the aqueous buffer. One of the shortcomings of the micellar aggregates is their incompatibility with the presence of higher than 20–30% organic cosolvents. In addition, the high molecular weight of the PSP makes them more compatible with MS detection, which

Chem* 2005;77:1672–1683; reprinted with permission.

is a significant potential advantage. Figure 15.3 illustrates the MEKC separation of an enantiomeric mixture of β -blockers with both the UV and MS detection using a chiral PSP (poly-L-SUCL) (poly(sodium N-undecenoxy carbonyl-L-leucinate)). Some PSP are not fully compatible with UV detection and lower efficiencies could be observed with certain PSP due to higher polydispersity and slow mass transfer kinetics. Another potential advantage of PSP is the possibility of extending the range of selectivity through control of the chemical composition and structure of the polymers (see below) [1–5,12].

The use of nanoparticles as PSP in MEKC has only been investigated in recent years. For examples, applications of polymeric, molecularly imprinted, silica, gold nanoparticles as well as CNTs have been reported. The CNT would have to be functionalized (e.g., with carboxylate groups) or be dispersed in SDS solutions to be used as PSP in EKC. Several recent publications have reported the applications of CNT and fullerene PSP for the separation of caffeine and theobromine, purine and pyrimidine, DNA fragments, anti-inflammatory drugs, enantiomers, and polyaromatic hydrocarbons (PAH) [26–31]. An example of the application of CNT is shown in Fig. 15.4.

Suspensions of silica nanoparticles in EKC have been reported for the separation of phenolic compounds, polyaromatic hydrocarbons, steroids, and aromatic acids [26–33]. Gold nanoparticles have been used in polymeric solutions of poly(ethylene oxide) (PEO) for the separation of double-stranded DNA fragments up to 48.5 kbp [34,35]. Note that the separation mechanism in this case is molecular sieving, which is different

Figure 15.4 EKC separation of chlorophenols with carbon nanotubes. In (a) absence and (b) presence of surfactant-coated single-walled carbon nanotubes (SC-SWNTs) (3.2 mg/L). The background electrolyte (BGE) was 25 mM sodium hydrogen phosphate, 15 mM sodium tetraborate, 100 mM SDS, and 6% ethanol at pH 7.95. Other operating conditions: capillary 30 cm_75 mm i.d., 15 kV, 201 C. Peaks: (1) 2,6-dichlorophenol; (2) 3,5-dichlorophenol; (3) 2,3-dichlorophenol; (4) 2,5-dichlorophenol; (5) 3,4-dichlorophenol; (6) 2,3,5-trichlorophenol; (7) 2,4,5-trichlorophenol; (8) 2,3,6-trichlorophenol; and (9) pentachlorophenol. *Source*: Ref. 29; reprinted with permission.

from EKC, where differential solute partitioning into a pseudostationary phase is the main driving force for the separation process.

15.4.3 Mixed Micelles

For certain complex mixtures of structurally similar solutes, one might not be able to find a suitable surfactant type that provides adequate resolution. This is typically due to a lack of selectivity and/or narrow elution window. In these situations, the use of mixed micelles (or mixed surfactant–polymer) can lead to enhanced separations. Mixing surfactants with different interactive properties can lead to great changes in selectivity for a given mixture. Selection of optimum composition would then be crucial in improving the quality of separation. The size of the elution window for certain mixed micellar systems is often larger than that for the individual constituent surfactants. Retention factor and selectivity change with the mole fraction of surfactants in the mixed micelles. Efficiency of the mixed micellar systems is often not much different from those of the single surfactant systems; however, in a few cases, loss of efficiency has been observed. Various combinations of different surfactants such as bile salt/anionic, anionic/zwitterionic, cationic/zwitterionic, fluorocarbon/anionic, anionic/nonionic, cationic/cationic, anionic/cationic, bile salt/bile salt, and nonionic/nonionic (for charged solutes) have been used in MEKC [1–5].

15.4.4 Organic Modifiers

Modifiers such as organic solvents, CDs, and urea are typically incorporated in the aqueous buffers of MEKC in order to reduce the retention factors of strongly bound solutes to micelles. Their presence can also lead to wider elution ranges and/or higher selectivity. Their use in MEKC separations, however, has been mostly for improving the separations of hydrophobic compounds that interact strongly with micelles and elute at or near migration time of micelles. The main role of organic modifiers in MEKC has been to reduce retention factors of highly hydrophobic solutes to within or near the optimum range. Typically, inclusion of organic solvents leads to an increase in the size of the elution window. As a result, resolution in MEKC can be enhanced at the expense of longer analysis times. The concentration of organic solvents would have to be limited (typically $\leq 20\%$) in order to maintain the integrity of micelles. The use of polymeric phases will provide an opportunity to investigate the role of organic solvents over a wider range of concentrations.

In addition to typical organic solvents, the use of other modifiers such as urea and glucose has also been reported. Urea reduces the interactions of hydrophobic compounds with micelles by increasing their solubility in the aqueous solutions. Retention factors of hydrophobic compounds in micellar solutions are therefore decreased dramatically. The size of the elution window has also been shown to increase with the addition of urea to MEKC systems. Another type of modifier that has been used in MEKC is CDs. In CD-modified MEKC (CD-MEKC), the hydrophobic cavity of CDs provides an alternative site of interaction to micelles for the hydrophobic solutes. Since uncharged CDs migrate at the EOF velocity and in the opposite direction of anionic SDS micelles, the net retention factor of solutes decreases in the presence of CDs. As a result, hydrophobic solutes that would otherwise elute with micelles can be better

separated. In addition, CDs introduce a shape selectivity effect that is beneficial for the separation of structural isomers [1–5].

15.5 CHARACTERIZATION AND CLASSIFICATION OF PSEUDOSTATIONARY PHASES

The first attempt for characterization and classification of the chemical selectivity of pseudostationary phases in MEKC was reported in 1990's using linear solvation energy relationships (LSERs) [36–38]. Since then, the LSER methodology has been extensively used for achieving a better understanding of the underlying interactions that control retention and selectivity of various types of micelles, block copolymers, polymerized micelles, mixed micelles, organically modified micelles, as well as vesicular and liposomes. The retention factor, k , in MEKC can be described by the general LSER model as follows:

$$\log k = c + vV + bB + aA + sS + eE \quad (15.8)$$

The LSER models quantitatively describe the contributions of hydrophobic/dispersion (vV term), type A hydrogen bonding (bB term, micellar phase as a HBD), type B hydrogen bonding (aA term, micellar phase as a HBA), dipolarity (sS term), and polarizability (eE term). Solute properties are described by the McGowan volume (V), HBA strength (B), HBD strength (A), dipolarity (S), and polarizability (E). The interactive properties of the micellar pseudophase are described by coefficient v , a measure of cohesiveness and dispersion interactions, coefficient b that is a measure of the HBD strength, coefficient a that is proportional to the HBA strength of the micelles, s that describes dipolarity, and e that is a measure of the affinity of micelles for σ and π electrons of solutes, and c is the regression constant. The LSER analysis clearly indicates that while the hydrophobic interaction (as quantified by the vV term) is the main driving force for retention in MEKC, the main source of selectivity variations between pseudophases is their hydrogen-bonding donor strength (the b coefficient) followed by hydrogen-bonding acceptor strength and dipolarity/polarizability interactions.

Fu and Khaledi have developed a novel micellar selectivity triangle (MST) to characterize and classify the chemical selectivities of pseudophases in EKC [22,23]. The MST scheme was devised based on the LSER parameters for construction of new, normalized scales for hydrogen-bonding (donor and acceptor) strengths, dipolarity, and polarizability of pseudophases and MST plots can be used to readily visualize the relative strength and classification of pseudophases based on their interactive properties. Figure 15.5 illustrates the comparison of the selectivities of over 70 pseudophases in terms of their hydrogen-bonding basicity, hydrogen-bonding acidity, and dipolarity and shows that the MEKC pseudophases clustered into four general groups. Group A consists of the SDS micelles and its analogs plus some mixed micelles containing SDS; group B consists of stronger HBD pseudophases such as LiPFOS micelles in single and mixed format with other surfactants and organic modifiers; group C consists of HBAs such as CTAB micelles, bile salts, microemulsions, as well as biphasic partitioning system of octanol–water; and group D, which is slightly stronger acceptor

Figure 15.5 Micellar selectivity triangle for characterization and classification of various micellar, polymeric, vesicular, and mixed pseudophases. *Source:* Ref. 22; reprinted with permission.

and has wider dipolarity range, consists of polymeric micelles of AGENT as well as some CTAB-modified micelles.

An advantage of MEKC is the feasibility and flexibility of controlling selectivity through adjusting the composition of the pseudophase. The MST scheme facilitates the selection of optimum pseudophases based on their selectivities. For example, Fig. 15.6 shows that solvation properties of SDS, CTAB, and LiPFOS micellar systems could be significantly changed through addition of organic modifiers hexafluoroisopropanol (HFIP) (a strong HBD) and pentanol (HBA). The two organic modifiers, PeOH and HFIP, mainly affect the hydrogen-bonding capability of micelles; thus, it is interesting to monitor the migration behaviors of HBA and HBD solutes in the selected micellar phases. Naturally, all HBD solutes have measurable HBA capability as well. Figure 15.7a–c shows the changes in retention patterns on addition of HFIP and PeOH to SDS micelles. As illustrated, on the addition of HFIP, the SDS micelles become a stronger HBD and have stronger interaction with solutes that have HBA groups, while addition of PeOH would enhance the HBA strength of the micelles and result in stronger interactions with HBD solutes.

15.6 DETECTION AND SENSITIVITY ENHANCEMENT

The detection systems for MEKC (and CE in general) are very similar to those used in HPLC. Absorbance detection is the most commonly used due to convenience, capability of detecting a wide range of compounds, feasibility of operation for on-column

Figure 15.6 MST for three micelles and six modified micellar systems. *Source:* Ref. 22; reprinted with permission.

detection, robustness, and good linearity. However, due to the exceedingly small peak volume (in nanoliter range), peaks must be detected in the capillary (i.e., on-column detection). Subsequently, the detection sensitivity of absorbance detection is modest (in micro-molar range) due to small light path length (which is the capillary diameter, typically 50–75 μm) and very small injection size. Detection path length (thus sensitivity) could be enhanced through the use of bubble cell [1–5]. Laser-induced fluorescence (LIF) has significantly better detection sensitivity (in subnanomolar range), albeit narrower scope of application as fewer classes of compounds are inherently fluorescent. Attachment of various fluorophore moieties to the parent compound would extend the range of applications of LIF detection of wider classes of compounds. Electrochemical detection is readily compatible with the CE techniques and offer great sensitivity for certain groups of compounds such as neurotransmitters. Unfortunately, MEKC has limited compatibility with MS detection due to the presence of high concentrations of surfactants in the buffer solution. The use of partial filling method, fluorinated surfactants, or polymeric pseudophases has been reported to improve the situation [1–5].

Owing to poor concentration sensitivity (LOD) in MEKC (and CE in general), on-line concentration of samples before the separation process is necessary for trace analysis. The two widely reported methods for sample preconcentration are based on stacking and sweeping mechanisms [1–5,39].

Figure 15.7 Chromatograms of the separation of 20 aromatic solutes composed of hydrogen-bond donors (HBDs): (1) resorcinol; (2) phenol; (7) 3-chlorophenol; (10) 4-ethylphenol; (12) 3,5-dimethyl phenol; and (15) 4-iodophenol. Hydrogen-bond acceptors (HBAs): (3) phenethyl alcohol; (5) nitrobenzene; (6) acetophenone; (8) methylbenzoate; (9) benzyl chloride; (14) 4-chloroacetophenone; and (16) methyl-2-methyl benzoate. Nonhydrogen-bond donors (NHBDs): (4) benzene; (11) toluene; (13) chlorobenzene; (17) ethylbenzene; (18) 4-chlorotoluene; (19) naphthalene; (20) propylbenzene. Micellar phases IDs: (a) 40 mM SDS, (b) 40 mM SDS/400 mM MPeOH (4.34% v/v), and (c) 40 mM SDS/400 mM HFIP (4.16% v/v). *Source:* Ref. 22; reprinted with permission.

15.7 MICROFLUIDIC MEKC

Microfluidic platform offers unique advantages over capillary tubes in MEKC (and CE) separations. The exceedingly smaller dimensions of separation channels in microchips as compared to capillary tubes are much more effective in dissipation of joules heating, thus allowing the use of much higher electric field strength and require significant reduction in the sample injection size. This results in higher separation efficiencies as well as significant reduction in analysis times from minutes to seconds. In addition, the microchip platform greatly facilitates designing parallel analysis (or separation) for increasing sample throughput, integration of sample manipulation and separation, as well as combining orthogonal separation techniques for two- or multidimensional separations for enhancement of peak capacity for resolving complex samples [40].

Ramsey's group first reported MEKC separations on microchips and investigated the effects of geometry and dimensions of separation channels. Using the straight channel design would allow a short separation length where high field separations can be performed. For example, a mixture of three coumarins were separated in <3 s using an electric field strength of 500 V/cm over a distance of 1.3 cm [41–44]. While the shorter separation channels and higher electric field strengths are desirable for achieving very fast separations of relatively simple mixtures, longer separation channel lengths are needed to generate larger absolute efficiencies for more complex and challenging mixtures. Increasing channel lengths on microchips can be achieved by incorporating turns in channel designs such as the use of serpentine and spiral geometries. However, it was determined that the turns in the separation channels could introduce additional band dispersion through “racetrack effect” as the molecules on the inside wall travel a shorter distance than those on the outer walls. New changes in microchip design

Figure 15.8 Image of a microchip with a spiral separation channel. The reservoirs on the interior of the spiral were replaced by a single reservoir located at the injection cross (dashed circle) for the experiments reported here. The small circles are the locations of the detection points from outside to inside 0.25, 11.9, and 22.2 cm. The inset is a magnification of the injection cross and parts of the spiral channel. The buffer, sample, and sample waste channels are 219- μm wide (half-depth) for all their length except for the last 500 μm before the injection cross where they narrow to only 40 μm (half-depth). The separation channel was 24.9-cm long and 40- μm wide (half-depth). The black arrows on the inset indicate the vertexes of the polygonally shaped channels. *Source*: Ref. 43; reprinted with permission.

Figure 15.9 MEKC separation of 19 TRITC-labeled amino acids in a 10 mM sodium tetraborate/50 mM SDS buffer with 10% (v/v) 2-propanol. The field strength was 770 V/cm, and the detection point was 11.87 cm from the injection cross. The peak locations of the amino acids are indicated by their standard one-letter abbreviations. *Source*: Ref. 43; reprinted with permission.

can be incorporated to minimize this geometrical band broadening effect; for example, by reducing the width of the channel in the turn or increasing the radius of the turn. Figure 15.8 illustrates the microchip spiral design with a separation length of about 25 cm. Figure 15.9 shows the MEKC separation of 19 tetramethylrhodamine isothiocyanate (TRITC) amino acids in <3 min using the spiral microchip with a field strength of 770 V/cm and channel length of 11.87 cm between the injection and detection. The separation efficiency is over 280,000 with a minimum resolution of 1.2 between adjacent peaks.

15.8 TWO-DIMENSIONAL MEKC SEPARATIONS

In multidimensional separations, different techniques with orthogonal separation mechanisms are combined to enhance peak capacity and achieve the necessary resolving power for complex mixtures as in proteomics applications. Theory predicts that the peak capacity of a multidimensional separation method equals the product of the individual peak capacities of the constituent orthogonal methods [45–51]. There are three main orthogonal mechanisms based on solute hydrophobicity (using RPLC or MEKC), charge (ion exchange LC or CZE), and size (size exclusion LC or capillary sieving electrophoresis). The widely used conventional two-dimensional (2D) gel electrophoresis is a powerful separation methodology with high resolving power where solutes are

Figure 15.10 Image of a microchip with a serpentine channel for two-dimensional separations. Injections were made at valve 1 (V1) for the first-dimension MEKC separation and at valve 2 (V2) for the second-dimension CE separation. The sample was detected 1-cm downstream from V2 at point D using laser-induced fluorescence. The reservoirs are labeled sample (S), buffer 1 (B1), sample waste 1 (SW1), buffer 2 (B2), sample waste (SW2), and waste (W). The channels and reservoirs were filled with black ink for contrast. *Source*: Ref. 49; reprinted with permission.

separated based on charge and size in the two dimensions. However, the technique has the disadvantages of being slow, labor intensive, and not quantitative. Over the past two decades, researchers have investigated 2D methods by combining a variety of HPLC and/or CE techniques in series, where the sample bands from the first dimension are transferred sequentially into a second dimension. A great majority of the 2D separations have involved the combination of different LC methods or LC in one dimension and an electrophoretic technique (IEF or CE) in the other dimension. There are only a few 2D separation reports where both dimensions are CE methods. In a handful of reports, MEKC has been used as one of the dimensions where solutes are separated based on their hydrophobicity.

Sheng and Pawliszyn [46] designed a 2D system by combining MEKC as the first dimension and CIEF as the second dimension using a 10-port valve as an interface for the separation of protein digests [46]. Hu *et al.* [47] analyzed protein expression in single mammalian cell using a 2D system with capillary sieving electrophoresis in the first dimension for size-based separation and MEKC in the second dimension and LIF for sensitive detection [47].

A major challenge in performing 2D capillary-based CE separations is interfacing the capillaries and independently controlling the electric fields in each dimension. On the other hand, microchip platform is much more suitable for performing two (and multi)-dimensional electrophoretic separations, as different channels can be readily connected and voltages at various locations can be easily monitored to control the flow of solutions and sample zones between different channels. Ramsey and coworkers reported 2D separation of protein digests using microfluidic devices where peptides were separated by MEKC in the first dimension followed by zone electrophoresis (CE) in the second dimension [48,49]. The microchip design for 2D MEKC–CZE separation of protein digests is illustrated in Fig. 15.10, where a 19.6-cm-long serpentine channel is used for MEKC separation followed by rapid CE separation in the second dimension using a short 1.3-cm-long straight channel. A peak capacity of 4200 was observed for the separation of the bovine serum albumin (BSA) tryptic digest mixture (shown in Fig. 15.11). Note that the timescale for the MEKC dimension is <15 min, while it is only around 1 s in the CE dimension. The electric field strength for MEKC was 200 and 2400 V/cm for the second CE dimension. The combination of short channel length and high electric field strength ensures rapid separation to avoid remixing of separated zones in the second dimension.

Soper's group reported 2D separations of proteins on microchips made of poly(methyl methacrylate) (PMMA) with SDS-PAGE for size-based separation in the first dimension and MEKC separation in the second dimension [50]. The proteins were labeled with a fluorescent tag and LIF was used for high sensitivity detection. Initially, they used the 2D system to separate a sample of 10 proteins with a molecular weight range of 38–110 kDa. The separation was completed in 12 min and the method provided a peak capacity of 1000. More recently, they reported comprehensive 2D SDS-CGE $\times$ MEKC separation of a complex protein mixture in fetal calf serum on a cross-design PMMA microchip (Fig. 15.12). The separation was completed in <30 min with an average peak capacity of 2600. The results were compared with that using conventional 2D gel electrophoresis, which is a combination of IEF and SDS-PAGE. The 2D microchip separation was 60 $\times$ faster with a peak capacity three times of the conventional method.

Figure 15.11 Two-dimensional separation of a bovine serum albumin tryptic digest. The projections of the two-dimensional data onto each axis are shown. Spots marked with a “T” represent unreacted 5-TAMRA dye. The dotted line illustrates correlation in the separation mechanisms. *Source:* Ref. 49; reprinted with permission.

15.9 CONCLUSIONS

EKC has matured into a microscale separation technique since its first introduction in 1984. The technique offers unique capabilities such as high resolving power, fast analysis time, availability of a wide range of pseudophases, and flexibility of rapidly adjusting the pseudophase composition for optimizing separation selectivity and enhancing resolution. In addition, the possibility of calculating micelle–water partition coefficients from solute structure and subsequently retention factor in MEKC is quite powerful for rapid optimization and enhancement of separation of complex mixtures. Significant progress has been made in synthesizing new pseudophases (especially polymeric and nanoparticles), and this trend will likely continue in the coming years. The wide range of selectivities in MEKC would be a great asset in 2D separations.

Figure 15.12 (a) Topography of the 2D microchip used for these studies. The channels were 50- μ m deep and 20- μ m wide in all cases. The first- and second-dimension channels were 7 cm (filled with gel media) and 6 cm (filled with MEKC buffer), respectively, in terms of their total column lengths. The effective column lengths for the first and second dimensions were 6 and 5 cm, respectively. (b) Diagram of the in-house constructed LIF system used for the separation. *Source*: Ref. 51; reprinted with permission.

The microfluidic platforms are ideal for interfacing two or more orthogonal electromigration techniques. Finally, much progress has been made in interfacing MS detection with MEKC. However, more work is needed before MEKC-MS comes to maturation for use in routine analytical applications.

16.1 SUMMARY

Liquid chromatography-tandem mass spectrometry (LC-MS/MS)-based methodology provides the most sensitive and specific methodology available for the analysis of small molecule drugs and endogenous metabolites in biofluids such as serum and plasma. However, the extraction and concentration of samples before the analysis represents a major hurdle for the implementation of routine assays and for assays when there are a large number of samples such as in drug disposition studies. This chapter provides a survey on the use of four different direct injection techniques that have been employed over the last decade for the analysis of biofluid samples. Specifically, background information, together with applications of solid-phase extraction (SPE), restricted access media (RAM), monolithic chromatography, and turbulent-flow chromatography have been reviewed. One of the major techniques for direct biofluid analysis utilizes on-line SPE. This is because a major drawback of off-line SPE procedures is that they often require many steps before reaching a concentrated extract suitable for the analysis, of which only a small portion is actually injected onto the LC column. In contrast, on-line SPE offers numerous advantages including the ability to readily automate the analyses. SPE sorbents include traditional materials, such as chemically bonded silica, ion-exchange and carbon-based materials, and some novel sorbents, such as RAM, molecularly imprinted polymers, immunosorbent, and monolithic material. Interfering substances present in the biofluids are flushed to waste while the analytes are retained

on the bonded phase of the SPE cartridge. Small molecule analytes are then eluted on-line, through a switching valve onto the LC analytical column. Simultaneously with the analytical separation, an exchange of the cartridge or reconditioning of the precolumn can take place.

The term *RAM* was introduced to describe a group of phases that allow direct and repetitive injection of untreated biological samples into reversed-phase LC systems. Macromolecules present in the biofluid samples cannot access the adsorption sites of porous supports because of their molecular size and so they elute in the void volume of the column. The RAM supports permit the separation of analytes through a combination of size-exclusion and conventional hydrophobic or ion-exchange interactions, which allows the passage of small molecules and restricts the access of macromolecules such as proteins. Two of the most popular RAM stationary phases are those employing internal surface reversed phase (ISRP) and alkyl-diol-silica (ADS) phase and there is an extensive literature describing the use of these columns. An interesting relatively recent development has involved the preparation of RAM using immobilized antibodies for the rapid and selective capture of small analytes by immunoextraction, giving rise to materials referred to as *immunoaffinity (IA)-RAM*. To make the required IA-RAM, an antibody for the desired target was first immobilized onto porous silica, with antibodies at or near the outer surface of the support then being treated with papain (or a related agent) to release and remove their binding domains. This resulted in a RAM support in which only antibodies deep within the pores remained intact and able to bind to the target analyte. This IA-RAM approach could potentially be used with many different antibodies to small molecule analytes and so could be useful for the rapid separation of drugs from drug-protein complexes.

Monolithic stationary phases comprise porous channels rather than beads found in conventional stationary phases employed for LC separations. They are typically prepared using a simple molding process carried out within the confines of a capillary. Monolithic stationary phases provide high rates of mass transfer at lower pressure drops, which enables much faster separations to be conducted when compared with conventional stationary phases. In addition, the nature of the pores in the monolithic phase allows easy permeability for large molecules. This means that monolithic columns can be used for direct biofluid analyses either as conventional LC columns or as sorbents in SPE columns for the extraction and concentration of small molecules. Turbulent-flow methodology was introduced specifically for the direct injection of biological samples without previous extraction or treatment onto an LC column packed with large particles. These large particles have an additional level of selectivity through different stationary phase chemistries (such as reversed phase or ion exchange) that can be added. Conventional LC methodologies employ parabolic flow profiles, while turbulent-flow LC (as its name implies) promotes turbulence in a packed column bed. The stream of mobile phase in the column moves so rapidly that it creates vacillating eddies within the stationary phase, which then cause flow equalization across the column. This results in a mobile phase front profile that is more like a plug than the parabola found in conventional LC separations. The eddies are also able to promote cross-channel mass transfer by convection within the interstitial spaces of the packed column bed. The use of fast mobile phase flow rates coupled with a plug flow profile results in an increase in the rate of change of the sample concentration gradient, thus increasing the effective diffusion rates within the pores. This turbulent-flow motion supports a more uniform velocity profile across the diameter of the column and controls effective

diffusion of the solutes. Therefore, analyte molecules can move quickly into and out of the pores and packing particles, which means that rapid chromatography can be conducted. The impressive sensitivity that has been attained with two-dimensional (2D) turbulent-flow LC-MS/MS suggests that it will be a powerful method for future routine applications for direct plasma and serum analyses of drugs and their metabolites, as well as endogenous metabolites.

16.2 INTRODUCTION

There is a compelling need for rapid, sensitive, and specific methods to analyze small molecule drugs, their metabolites, and endogenous metabolites for pharmaceutical development, as well as biomarker, therapeutic, and metabolomic applications [1–5]. The analysis of drugs in biofluids such as serum and plasma represents an important component in the determination of the physiological performance of a drug [6,7]. Therefore, a substantial amount of research has been conducted to develop rapid high throughput methods for the direct analysis of drugs and their metabolites in biofluids. Stable isotope dilution LC-MS/MS provides powerful bioanalytical methodology that combines high specificity with high sensitivity [8–10]. In spite of many advantages that have accrued due to recent advances and innovations in the area of instrumentation and dedicated software support, analysis of biofluid samples by LC-MS can be challenging and very time consuming [11]. One approach for improving sample throughput is to conduct direct on-line analysis of biofluid samples with no off-line extraction and purification. Such methods offer the advantage of reducing sample preparation steps and enabling effective preconcentration and cleanup of biological fluids. These procedures can also be readily automated, which reduces the requirements for handling potentially infectious biomaterial, improves reproducibility, minimizes sample manipulations, and limits potential contamination [12]. This chapter provides an overview on the use of four different direct injection techniques that have been employed over the last decade for the direct analysis of biofluid samples. Specifically, underlying principles involved in the application of SPE, RAM, monolithic chromatography, and turbulent-flow chromatography for direct analyses are addressed. A major issue that arises from direct analyses is the propensity for components of the biofluids to either suppress or enhance ionization in the analyzer region of the mass spectrometer [13]. Therefore, methodology for assessing such effects on different commonly used LC-MS ionization techniques is discussed [13,14]. A number of excellent review articles have appeared over the last decade describing the application of various methodologies for the direct analysis of biofluid samples [11,12,15–20]. Therefore, this chapter is focused primarily on recent advances that have been made in the application of the various direct on-line methods.

16.3 ON-LINE SPE

16.3.1 Background

Sample preparation is a major task in both regulated and unregulated bioanalytical laboratories. Sample preparation procedures significantly impact on assay throughput, data

quality, and analysis cost. Therefore, selecting and optimizing an appropriate sample preparation method is essential for successful method development using direct biofluid analysis methods [11]. Two of the major techniques that are employed utilize off-line SPE or on-line SPE. Significant drawbacks of off-line SPE procedures is that they can require many steps before reaching a concentrated extract suitable for the analysis, of which only a small portion is actually injected onto the LC column (Fig. 16.1) [21,22]. In contrast, on-line SPE offers numerous advantages including the ability to completely automate the analyses [22–24]. The on-line SPE approach involves the injection of a biofluid sample directly into an SPE cartridge, which retains the relevant analytes. SPE sorbents include traditional materials, such as chemically bonded silica, ion-exchange and carbon-based materials, as well as some novel sorbents, such as RAM, molecularly imprinted polymers, immunosorbents, and monolithic material [25]. Interfering substances present in the biofluid are flushed to waste, while the analytes are retained on the bonded phase of the SPE cartridge. They are then eluted on-line, through a switching valve onto the LC analytical column [23]. Simultaneously with the analytical separation, an exchange of the cartridge or reconditioning of the precolumn can take place.

Direct analysis of biofluid samples using SPE-based methodology has a long history because it can significantly increase sample throughput [12]. The overall methodology for LiChrograph OSP-2 (On-line Sample Preparation Unit, Merck, Darmstadt, Germany) Microlab SPE (Hamilton, Reno, NV, USA), and the widely used PROSPEKT (Programmable On-line Solid Phase Extraction Technique, Spark Holland BV, The Netherlands) systems have been discussed extensively in previous review articles [26–28]. Therefore, this chapter provides an overview of the symbiosis system developed by Spark Holland BV [29,30]. The system allows the use of

Figure 16.1 Comparison between on-line and off-line SPE methodology. *Source:* Reprinted with permission from Mitchell *et al.*, 2010 [22]. (See color insert.)

two different extraction mechanisms on two separate disposable SPE cartridges in one sample run, which can significantly improve upon methods that employ single SPE cartridges. Disposable cartridges help to eliminate sample-to-sample carryover problems that can sometimes be observed when columns are reused, particularly for low level analytes. The Symbiosis system can handle sample volumes from 10 μ L to 10 mL and can add, mix, and dilute samples before the analysis. The principles of extraction are essentially the same as off-line SPE. However, the system design allows the SPE eluate to be directly injected onto the chromatography system, thus removing the need for any evaporation (Fig. 16.1). By avoiding evaporation steps, it is possible to significantly cut down on the amount of time required for the sample analysis. In addition, the ability to use two separate liquid flows for the extraction and chromatography steps significantly reduces the potential for carryover from sample to sample. This can be a particular problem when analyzing large concentration ranges of drugs and endogenous metabolites that are present in plasma and serum samples. Importantly, there is a large variety of stationary phases available for the SPE cartridges, which can help in the development of highly selective on-line extraction methodology.

The development of analytical methodology for sophisticated on-line SPE extractions requires a substantial amount of time to optimize all of the conditions. A particular advantage of the Symbiosis system is that the SPE cartridges can be washed with heated solvents. This can be useful when washing with organic solvents is precluded by the polarity of the analytes. Parameters such as elution time, elution flow rate, solvent polarity, and type of stationary phase have to be modified for different analytes. A recent study demonstrated that the performance of assays with on-line extraction was essentially identical with that obtained by off-line SPE extraction [22]. Therefore, the benefits generally only accrue for large sample batches. Consequently, off-line SPE extraction methodology generally remains the method of choice for small numbers of samples. However, for volatile or unstable samples, on-line methodology is preferable even for small sample numbers [29]. Both on-line and off-line SPE-LC-MS configurations can result in significant matrix effects, which depend on whether electrospray or atmospheric pressure chemical ionization (APCI) is being used and the particular extraction support that is utilized [31]. Therefore, it is necessary to assess the amount of suppression or enhancement of ionization that is occurring with different batches of plasma or serum samples [13].

16.3.2 Applications of On-Line SPE

A validated method for on-line SPE coupled with LC-tandem mass spectrometry (MS/MS) for analysis of the anxiolytic drug bromazepam in human plasma provides an illustration of how direct biofluid analyses can be conducted [32]. The method involved addition of carbamazepine internal standard, vortex-mixing, centrifugation, and injection of 100 μ L of the supernatant. Analytes were ionized using positive electrospray mass spectrometry then detected by multiple reaction monitoring/MS. The calibration curve was linear from 1 ng/mL (limit of quantification) to 200 ng/mL with LC retention times for bromazepam and carbamazepine of 2.6 and 3.2 min, respectively. This automated method was successfully applied in a bioequivalence study of two tablet formulations. The comparison of different experimental conditions for establishing a dissolution profile *in vitro*, along with the bioavailability data that were generated,

made it possible to propose rationally based experimental conditions for a dissolution test of bromazepam tablets.

In the field of environmental toxicology, SPE-LC-MS/MS was employed for quantifying trace levels of 18 perfluorinated chemicals (three perfluorosulfonates, eight perfluorocarboxylates, and seven perfluorosulfonamides) in serum [29]. After dilution with 0.1M formic acid, an aliquot of 100 μ L of serum was injected into a commercial column-switching system that allowed for concurrent SPE and LC-MS/MS analyses. Analytes were concentrated on a C18 SPE column and the eluates then automatically injected on a reversed-phase C8 analytical LC column. Excellent recovery was achieved for all analytes including the volatile sulfonamide derivatives, which could not be analyzed using traditional off-line SPE methods. The high throughput and low limits of detection (0.05–0.8 ng/mL) using a small sample volume and isotope dilution quantification make this method suitable for large-scale epidemiological studies.

A novel approach for on-line introduction of internal standard for quantitative analysis using LC-MS/MS was developed for use with on-line SPE methodology [33]. In this approach, the analyte and internal standard were introduced into the sample injection loop in different steps. The analyte was introduced into the injection loop using a conventional autosampler (injector) needle pickup from a sample vial, whereas the internal standard was introduced into the sample injection loop on-line from a microreservoir containing the internal standard solution. As a result, both analyte and internal standard were contained in the sample loop before the injection into the column. This new technique was applied for direct analysis of model compounds in rat plasma using on-line SPE-LC-MS/MS quantification. The assays yielded accuracy (85–119%), precision (2–16%), and analyte recovery comparable to those obtained using off-line internal standard introduction. Furthermore, on-line internal standard introduction allowed for nonvolumetric plasma collection and direct analysis without the need of measuring and aliquoting a fixed sample volume before the on-line SPE-LC-MS/MS analysis. Therefore, this methodology enabled direct plasma analyses to be conducted without any sample manipulation and preparation. On-line SPE coupled with capillary LC-ESI-MS was employed to improve the sensitivity for quantification of the antidepressant and anorectic drug fluoxetine (valium) in human plasma [34]. Before injection, the plasma was spiked with metronidazole (internal standard) and mixed with ammonium formate buffer for effective chloroform liquid–liquid extraction. The method was validated in the range 5–60 ng/mL fluoxetine. The method was then used to determine the amount of fluoxetine in a healthy male 14 h after an intake of one capsule of flutrin, which contains 20 mg fluoxetine/capsule. The use of capillary LC increased the sensitivity by a factor of similar to 100 when compared with conventional LC systems.

The analysis of endogenous metabolites in plasma by direct SPE-LC-MS is exemplified by the studies conducted on the analysis of steroids in serum [35]. Following protein precipitation of 100 μ L serum, on-line SPE and chromatographic separation were performed for 13 steroids in 1.8 min. Analyte identities were confirmed by the characteristic fragmentation patterns observed by MS/MS analyses in a quadrupole ion trap. The total run time of the method was 4 min. Limits of quantitation ranged between 50 pg/mL for testosterone and 48 ng/mL for dehydroepiandrosterone sulfate. The method was linear up to 7000 ng/mL for dehydroepiandrosterone sulfate, 500 ng/mL for cortisol, 125 ng/mL for 11-deoxycortisol, and 25 ng/mL for aldosterone, 17-hydroxyprogesterone, progesterone, testosterone, androstenedione, and β -estradiol, respectively. Accuracy ranged between 80% and 114%. Between-day variance at three

different concentration levels was $<15\%$. Excellent correlations with immunoassays were observed for testosterone, cortisol, and β -estradiol. Therefore, this novel on-line SPE-LC-MS/MS platform offers a very fast and reliable method for the quantification of steroid patterns for relatively routine laboratory applications. However, the limits of detection would need to be substantially lower for research applications such as the determination of breast and prostate cancer risk [3,36].

Recently, an on-line SPE-LC-MS/MS method was optimized for quantification of the anti-HIV (human immunodeficiency virus) peptide sifuvirtide in human plasma [37]. The SPE sorbents, loading buffer composition, and other aspects of the on-line SPE column were investigated in detail for efficiently extracting the interesting peptides and simultaneously discarding the large amount of proteins from the plasma. Method validation revealed a linear calibration curve that covered a wide range of 6.1–6250 ng/mL, with excellent correlation coefficients. The lower limit of detection with a signal-to-noise ratio >10 was 6.1 ng/mL. Impressively, more than 900 samples from a clinical trial were analyzed in a single week because of the rapid run time of 6.5 min for individual samples.

16.3.3 Background and Applications of Miniaturized SPE (μ -SPE) Cartridges

μ -SPE (micro solid-phase extraction) cartridges are available as a component of the RapidFire System (BIOCIUS Life Sciences, Wakefield, MA), which also uses innovative microfluidics technology. This system is emerging as a useful approach to direct biofluid analysis. Its utility was demonstrated by comparing a high throughput RapidFire MS System with a scintillation proximity assay [38]. The RapidFire System allows continuous SPE extractions to be performed in 5–10 s time intervals [39]. Thus, this technology performs rapid SPE purification of biofluids in 96 or 384 well plates followed by MS-based analysis [40,41]. Extracted analytes are rapidly eluted to a mass spectrometer after every SPE step, and analytes that are present in each well are quantified sequentially. Initial high throughput applications have focused on the analysis of enzyme incubation mixtures [38,41–43]. For example, a series of 120 compounds was evaluated for potential drug–drug interaction by incubating over a range of eight test concentrations and against a panel of six cytochrome P450 (CYP) enzymes, 1A2, 2C8, 2C9, 2C19, 2D6, and 3A4 [43]. The on-line SPE-MS/MS system reduced analysis time to <15 min per 96-well plate, translating to a 15-fold time savings compared to the 2-min LC/MS/MS method. There was an excellent correlation between this new rapid high throughput method and previous methods for the individual CYP enzymes.

The success of direct analyses of biofluids from enzyme assays using μ -SPE cartridges has encouraged investigators to test more challenging biofluids such as plasma. A presentation at the recent Applied Pharmaceutical Analysis meeting in Baltimore, MD explored the use of μ -SPE-based methodology for the high throughput direct analysis of drugs in plasma samples [44]. Encouragingly, the assay results from RapidFire-MS/MS analysis correlated well with the results from conventional LC-MS/MS analyses. Use of stable isotope labeled and structural analog internal standards effectively compensated for matrix effects. When the ion source conditions were optimized to minimize interference from an acyl-glucuronide metabolite, parent drug concentrations were comparable to those obtained from LC-MS/MS system. Therefore, co-eluting metabolites had a negligible impact on quantitation. Even though there were variable amounts of sample-to-sample carryover, no significant

impact on quantitation results was observed. Therefore, the μ -SPE-based RapidFire System might be a useful tool for high throughput MS quantitation of *in vivo*-derived biofluid samples in situations where large sets of samples justify the up-front burden of method development [44].

16.4 RAM

16.4.1 Background

The term *RAM* was introduced by the Desilets *et al.* to describe a group of phases that allows direct and repetitive injection of untreated biological samples into a reversed-phase LC systems [45]. Macromolecules present in the samples cannot access the adsorption sites of porous supports because of their molecular size and so they elute in the void volume of the column [46]. RAM supports permit the separation of analytes through a combination of size-exclusion and conventional hydrophobic or ion-exchange interactions, which allows the passage of small molecules and restricts the access of macromolecules such as proteins [47]. Macromolecular exclusion can be performed using a physical diffusion barrier based on the size of the pore or by a chemical diffusion barrier created by a network covering the surface of the support, which consists of covalently or adsorptive-bonded synthetic polymers, natural polymers, or proteins at the outer surface of the silica. It has been suggested that RAM sorbents can be divided into four groups: physical diffusion barriers with either unimodal, bimodal phases, chemical diffusion barriers with either unimodal, or bimodal phases (Fig. 16.2a) [28,47]. RAM stationary phases such as ISRP (Fig. 16.2b), semipermeable surface, ADS (Fig. 16.2b), shielded hydrophobic phase, mixed-function phase, and protein-coated silica have all been employed for LC-MS-based direct plasma analyses [46]. Commercial columns are available for each of these applications. The two most popular RAM stationary phases are those employing ISRP and ADS. A large number of applications, together with the commercially available columns that were used, have been described in the excellent extensive review by Souverain *et al.* [48].

An interesting relatively recent development has involved the preparation of RAM using immobilized antibodies for the rapid and selective capture of small analytes by immunoextraction, giving rise to materials referred to as *IA-RAM* [49]. To make the required IA-RAM, an antibody for the desired target was first immobilized onto porous silica, with antibodies at or near the outer surface of the support then being treated with papain (or a related agent) to release and remove their binding domains. This resulted in a RAM support in which only antibodies deep within the pores remained intact and able to bind to the target analyte. This IM-RAM approach could potentially be used with many different antibodies to small molecule analytes and so could be useful for the rapid separation of drugs from drug-protein complexes. It could also be particularly valuable for separating endogenous DNA bases such as 2'-deoxy-guansoine (dGuo) from 7,8-dihydro-8-oxo-dGuo (8-oxo-dGuo) in plasma samples. This would help prevent the artifactual formation of 8-oxo-dGuo when there is an excess of dGuo present [50]. The need for RAM capillary columns that could be used for low flow applications that enhance detection sensitivity was recognized by Jarmalaviciene *et al.* [51]. They have developed different strategies for the preparation of novel shielded polymeric reversed-phase monolithic material in the presence of different numbers

RAM phase	Diffusion barrier	Surface topochemistry	Type
	Physical	Homogeneous	A
	Physical	Heterogeneous	B
	Chemical	Homogeneous	C
	Chemical	Heterogeneous	D

of reactive groups and concentrations of the coating polymer. Inverse size-exclusion chromatography was used for investigation of the pore structure properties of the beds. The resulting RAM capillary columns were then applied for nanochromatography of biological fluids containing a mixture of the sedative benzodiazepine drugs nitrazepam and medazepam.

16.4.2 Applications of RAM

As might be predicted, RAM can be used as the solid support for both off-line and on-line SPE of small molecules in plasma as well as the stationary phase for LC separations [28,48]. There are many applications appearing in the current literature that use the RAM for this purpose rather than conventional LC procedures. A recent application described the use of an LC system that was equipped with an on-line dilution system for on-line SPE analysis [52]. Use of a six- to eightfold on-line dilution ratio for plasma samples resulted in almost quantitative recovery of both acidic and basic drugs from plasma. It was found that the relationship between the on-line dilution times and drug recovery efficiencies from plasma could be explained in terms of the binding constant between the drug and albumin. The applicability of this column-switching LC with an on-line dilution system and the effectiveness of the extraction procedure were confirmed by a simultaneous determination of the basic compound, ER-118585, and its metabolites in canine plasma.

Another interesting example of on-line SPE analysis involved the extraction of the proton-pump inhibitor, lansoprazole from plasma using an octyl RAM bovine serum albumin column (C-8 RAM BSA) [53]. Enantioselective LC separations were performed on an amylose tris(3,5-dimethoxyphenylcarbamate) chiral column. The method was applied to the analysis of the plasma samples obtained from nine volunteers who received a 30-mg oral dose of racemic lansoprazole and was able to quantify the enantiomers of lansoprazole in all the samples that were analyzed. RAM-based SPE extraction methodology has proved to be particularly useful for the analysis of the radioactive components in plasma taken during positron emission tomography (PET) measurements using [^{11}C]-labeled radiopharmaceuticals [54]. Plasma samples were analyzed directly, following a simple filtration, by the use of a small RAM SPE column, combined with a monolithic LC analysis in a column-switching system. Up to 4 mL of plasma could be analyzed by this method within 4.5–7 min in a fully automated process. A large number of samples could be analyzed during a 90-min PET scan. This method made it possible to conduct accurate determinations of the radioactive components in plasma even at 90 min after injection of a [^{11}C]-labeled radiopharmaceutical.

An important aspect of on-line RAM SPE for routine analyses is the ability to concentrate the sample into a small volume. Santos-Neto *et al.* found that the peak-focusing efficiency of the RAM SPE column was more effective in back-flush compared to fore-flush mode [18]. Their system was able to concentrate polar drugs and their metabolites reaching quantifiable results as low as 1 ng/mL utilizing a sample volume of only 333 nL of plasma. New column hardware was developed to circumvent clogging problems that were experienced with plasma injections. The glass fiber filter frit, which is commonly used, was replaced with a short piece of 20- μm internal diameter fused silica capillary tubing. The RAM SPE columns were then able to handle up to 60 injections without any deterioration in separation efficiency. The columns also had a

high loading capacity, making the saturation of the MS detector, the limiting factor on the linear dynamic range. Using this method, it was possible to simultaneously separate and detect 10 drugs and metabolites within 8 min.

A simple and rapid RAM-based LC-MS method was used for direct analysis of the antibiotic rifaximin in rat serum [55]. Separation of rifaximin from serum was achieved by the injection of rat serum onto a Supelco LC-Hisep LC column, which contains a shielded hydrophobic RAM stationary phase. The linear range of the assay was a 0.10–20 ng/mL of serum. The validated RAM-based LC method was successfully applied to pharmacokinetic studies of rifaximin in serum after oral administration to rats. RAM LC has also been employed for coupled-column separations [56]. A RAM bovine serum albumin RAM LC column was used in the first dimension in order to exclude macromolecules and retain small molecules. An amylose tris[(*S*)-1-phenylethylcarbamate chiral column was used in the second dimension. This fully validated method has provided the first example of the rigorous analysis of both enantiomers of the analeptic drug modafinil and its two major metabolites in plasma. The coupled RAM-chiral column method showed good linearity, precision, accuracy, sensitivity, and selectivity, allowing it to be used for pharmacokinetic studies. Importantly, the quality of the performance of both columns was maintained with over 280 plasma injections.

16.5 MONOLITHIC CHROMATOGRAPHY

16.5.1 Background

Monolithic stationary phases comprise porous channels rather than the beads found in conventional stationary phases employed for LC separations [12,16]. They are typically prepared using a simple molding process carried out within the confines of the capillary [57]. Monolithic stationary phases provide high rates of mass transfer at lower pressure drops, enable much faster separations and the nature of the pores allows easy permeability for large molecules (Fig. 16.3) [58]. This means they can be used for direct plasma analyses either as conventional LC columns [59,60] or as sorbents in SPE columns for the extraction and concentration of small molecules [20]. Silica-based monolithic stationary phases are prepared from tetraalkoxysilane by

Figure 16.3 (a) SEM-picture of the typical porous structure of monolithic silica columns. (b) The mesoporous structure of the silica skeleton. (c) The macropores or through-pores. *Source:* Reprinted with permission from Hayes *et al.*, 2000 [58].

a sol-gel method. This can provide either micrometer-size through-pores or high specific surface areas that are well suited for small molecules in LC modes. In contrast, organic polymer-based monolithic stationary phases including monolithic molecularly imprinted polymers have been applied to LC analysis of macromolecules and they have also been employed as sorbents for both on-line and off-line SPE extraction of plasma. The most commonly reported organic polymers are based on polystyrenes, polymethacrylates, and polyacrylamides. Monolithic phases have a number of potential advantages over more conventional silica-based particulate materials, as outlined in the excellent review by Saunders *et al.* [61]. Polymer monoliths can be adapted to many bioanalytical situations such as sample preparation and concentrations as well and capillary LC separations, which explains their increasing use for direct plasma analyses. These materials have some interesting properties when compared to more traditional particulate materials, such as their high permeability for liquids and biological samples, making them ideal for SPE applications.

16.5.2 Applications of Monolithic Chromatography

Many new applications on the monolithic SPE in sample extraction and concentration (as a sample extraction and concentration tool before more conventional LC separations) have appeared over the last decade [10,25]. A comprehensive review of the use of monolithic chromatography has appeared recently [20]. Although many of the

Figure 16.4 Schematic diagram of the on-line SPE monolithic LC/MS/MS configuration. Source: Reprinted with permission from Zang *et al.*, 2005 [62].

applications do not relate specifically to direct plasma analyses on a monolithic column itself, the examples that have been provided can be used as the basis for embarking on the use of this type of methodology. In an interesting example, Zang *et al.* developed on-line SPE LC/MS/MS assay using a monolithic LC column for the direct analysis of plasma samples containing multiple analytes [62]. A simple column-switching configuration that required only one six-port valve and one LC pumping system was employed for on-line plasma sample preparation and subsequent gradient LC separation using a monolithic Chromolith Speed ROD RP-18e (4.6×50 mm i.d., Merck) (Fig. 16.4). The method was found to perform satisfactorily for direct plasma analysis with respect to assay linearity, specificity, sensitivity, precision, accuracy, carryover, and short-term stability of an eight-analyte mixture in plasma. Gradient LC conditions were applied in order to separate the eight analytes that could not be readily differentiated by MS/MS analysis. With a run time for every injection of 2.8 min, a minimum of 300 direct plasma injections were made on one on-line SPE column without noticeable changes in system performance. Owing to the ruggedness and simplicity of this system, the authors suggested that generic methods could be easily developed for the analysis of a wide variety of small molecules in plasma in a high throughput manner without laborious off-line sample preparation.

A particularly good example of direct plasma analysis using monolithic LC-MS/MS is provided by the method developed by Hsieh *et al.* [15]. The method was employed for high-speed direct simultaneous determination of a drug discovery compound and its major circulating metabolite (M-72) in rat plasma. This methodology made use of flow programming and an alkyl-bonded silica rod column for fast macromolecule removal and chromatographic separation without the need for significant sample preparation. After 200 plasma injections on the monolithic silica column (50×4.6 mm i.d.), consistent column efficiency of approximately 39,000 theoretical plates per meter could be obtained together with reproducible retention times. The apparent on-column recoveries of 12 test compounds in rat plasma samples were $>90\%$. The direct plasma injection method was tested over a three-day period, where inter-day coefficients of variation of $<15\%$ were observed for both analytes.

16.6 TURBULENT-FLOW CHROMATOGRAPHY

16.6.1 Background

Turbulent-flow methodology was developed by Quinn and Takarewski specifically for the direct injection of biofluids without previous extraction or treatment onto an LC column packed with large particles [19]. These large particles have an additional level of selectivity through different stationary phase chemistries (such as reversed phase or ion exchange) that can be added. Conventional LC methodologies employ parabolic flow profiles, whereas turbulent-flow LC (as its name implies) promotes turbulence in a packed column bed. The stream of mobile phase in the column moves so rapidly that it creates vacillating eddies within the stationary phase, which then cause flow equalization across the column. This results in a mobile phase front profile that is more like a plug than the parabola found in conventional LC [63]. The eddies also promote cross-channel mass transfer by convection within the interstitial spaces of the packed column bed [63]. The use of fast mobile phase flow rates coupled with a plug flow

profile results in an increase in the rate of change of the sample concentration gradient, thus increasing the effective diffusion rates within the pores. This turbulent-flow motion supports a more uniform velocity profile across the diameter of the column and controls effective diffusion of the solutes. Therefore, analyte molecules can move quickly into and out of the pores and packing particles, which means that rapid chromatography can be conducted.

Typically, a biofluid sample is injected onto a turbulent-flow LC column at flow rates of between 1.5 and 5.0 mL/min. Initially, aqueous buffers are used as the mobile phase, so that small molecules are retained on the column through diffusion into the particle pores. The proteins that are present in the sample rapidly elute from the column and are washed to waste. Once the small molecules have been extracted from the biofluid into the stationary phase, they are then either eluted from the turbulent-flow column to a conventional analytical LC column in a 2D approach as described by Jemal [64], Wu *et al.* [65], and Chassaing *et al.* [66], or they are analyzed directly on the same column as described by Ayrton *et al.* [63]. Not surprisingly, the 2D approach has become the method of choice because it allows for much more selectivity as well as improved sensitivity through the use of low flow rates on the analytical column. For use of the turbulent-flow column as the initial extraction method, it has been recommended that the small molecule analytes should be eluted onto the analytical column using solvent that has been stored in a holding loop [19]. The holding loop should have a volume at least 10 times that of the turbulent-flow column and is typically filled with organic mobile phase (for reversed stationary phase) or pH buffered solutions (for ion-exchange phases) [19]. The use of switching valves to obtain optimal system performance is shown in Fig. 16.5.

A major issue with all biofluid assays is the degree of suppression or enhancement of ionization that can occur with LC-MS-based methodology [67]. This issue is extremely important when nonidentical or deuterium labeled standards are employed because there can be significant separation between the analyte and its relevant internal standard [68]. Suppression effects can potentially be problematic even with [^{13}C] and [^{15}N]-labeled internal standards because they can significantly affect the lower limit of quantitation. The current regulatory requirements include the need for the assessment and elimination of the matrix effect in bioanalytical methods that are submitted to the Food and Drug Administration [13]. These effects can be determined by infusing the analyte and observing the suppression and ionization caused by the LC effluent [14]. A robust procedure has also been described in which five different plasma lots are analyzed [13]. This makes it possible to determine the absolute effects for particular plasma samples or the relative effects with different plasma samples. The magnitude of matrix suppression and enhancement effects on ionization efficiency appears to be dependent on the actual mechanism of ionization. Under otherwise identical sample

Figure 16.5 (a) Loading step: turbulent-flow removed proteins from the plasma through the turbulent-flow (Turboflow) column while small molecules are retained. (b) Transfer step: flow from both pumps is combined through the T-rotor seal, which allows the loop contents to transfer the analytes retained on the turbulent-flow column into a stacked band on the analytical column. (c) Elution step: the analytes are eluted from the analytical LC column using an isocratic or gradient mobile phase. The turbulent-flow column is washed and the loop is filled and closed in preparation for the next injection. *Source*: Reprinted with permission from Chassaing and Robinson, 2009 [19].

extraction and chromatographic conditions, the matrix effect was absent when APCI was employed but very significant with electrospray ionization [13]. Therefore, a thorough consideration of the ionization technique that is employed can be an important component of the analytical development procedure. A fully automated turbulent-flow method for the analysis of antidepressants in serum investigated the suppression of plasma constituents [69]. This study revealed that all of the suppression occurred before the relevant analytes eluted from the column and illustrated the power of turbulent-flow extraction methodology (Fig. 16.6).

16.6.2 Applications of Turbulent-Flow Chromatography

The quantification of Vitamin D in serum and plasma is an important diagnostic test of nutritional status that is often performed by radioimmunoassay procedures. Stable isotope dilution LC-MS/MS is in principle more accurate and specific and can be employed for multiple vitamin D metabolites [2]. However, time-consuming methods are required for extraction and purification of vitamin D and its analogs, which have restricted the use of LC-MS approaches. The analysis of plasma and serum vitamin D is very challenging because the concentrations are often in the low ng/mL (low nM) range [2]. A turbulent-flow on-line extraction-based 2D method was reported recently for the analysis of 25-hydroxy vitamin D3 (25OHD3), and 25-hydroxy vitamin D2 (25OHD2), the two most important vitamin D metabolites [70]. The second dimension was conducted using a Hypersil gold aQ LC column (Thermo Fisher) coupled with APCI-MS. Assays were linear from 3.0 to 283 nmol/L for 25OHD3 and from 4.6 to

Figure 16.6 Study of the ion suppression phenomenon by means of continuous infusion of 20 antidepressants at 100 ng/mL and parallel injection of extracts of blank serum samples: the example of the nortriptyline and imipramine extracted-ion chromatograms. *Source:* Reprinted with permission from Sauvage *et al.*, 2006 [69].

277.9 nmol/L for 25OHD3 with chromatographic run times of only 1 min (Fig. 16.7). Importantly, no carryover or ion suppression was observed, lending further credence to the concept that APCI is less susceptible to matrix effects than other ionization techniques [13].

An area that offers significant future applications is in the field of metabolomic analyses because it is very difficult to analyze the polar metabolites without causing significant suppression of ionization as well as contamination of the ion source from plasma constituents [8]. A recent study has compared the use of protein precipitation with a 2D turbulent-flow LC-MS/MS approach [5]. This comparison has shown that turbulent-flow chromatography could be effectively used with a substantial reduction of the time required for sample handling. Furthermore, there were substantial differences in the overall metabolite profiles for the two methods. This was ascribed to greatly reduced amounts of phospholipids (ca. 10-fold reduction) for the turbulent-flow methodology compared with protein-precipitated samples. Interestingly, the majority of ions were detected in the mass range of m/z 200–400 compared with m/z 400–600 for the protein-precipitated samples. It was suggested that this could have been due in part to the loss of small molecules bound to proteins in the turbulent-flow method and suggest that a combination of both methods could maximize differences in metabolomic characterizations.

An impressive example of the sensitivity that can be attained with 2D turbulent-flow LC-MS/MS methodology was reported recently for the analysis of plasma testosterone [71]. Total analysis time was 1.15 min per sample when using the multiplexing system that was developed. Testosterone concentrations were measured directly from 150 μ L of serum or plasma without derivatization or liquid–liquid extraction. The lower limit of quantification was 300 fg/mL and the assay was linear up to 200 ng/mL. Furthermore, the method compared very well with an established radioimmunoassay. Therefore,

this high throughput method appears to be suitable for quantifying the expected low-testosterone concentrations seen in women, children, and hypogonadal males and for monitoring testosterone suppressive therapy in prostate cancer patients.

In the field of drug disposition, a recent article described a fully automated turbulent-flow 2D LC-MS/MS method for the detection of tricyclic antidepressant drugs (amitriptyline, desipramine, imipramine, and nortriptyline) in serum [72]. Human serum and an internal standard were injected directly onto a turbulent-flow Cyclone-P on-line SPE column (0.5×50 mm, Thermo Fisher). Following removal of serum proteins and other components the analytes were transferred to a Hypersil Gold C-18 (50×3 mm, Thermo Fisher) analytical column. Gradient elution was performed with water and acetonitrile each containing 0.1% formic acid. The antidepressant drugs were ionized and detected over a 3.5 min analysis time using electrospray-ionization/MS. Matrix effects were characterized and carryover, precision, linearity, recovery, and limits of detection and quantitation were evaluated. The limits of detection and quantitation for all drugs were <3 ng/mL and <20 ng/mL, respectively. Recoveries were between 97% and 114%. On the basis of the validation data, this specific, sensitive fully automated method can be employed for rapid quantitation of tricyclic antidepressants in serum.

16.7 CONCLUSIONS AND FUTURE DIRECTIONS

Over the last decade, the direct analysis of biofluid samples has become a realistic alternative to time-consuming off-line extraction and purification procedures [11,12,15–20, 65]. This evolution has resulted in essentially two different approaches (SPE and turbulent-flow chromatography) for use in combination with MS instrumentation. On-line SPE coupled with conventional LC-MS has become a very mature method with the ability to conduct efficient on-line purification coupled with disposable columns [11,29,30]. The solid-phase sorbents can be of the conventional modified silica supports as well as RAM and monolithic sorbents. Intriguing future directions of this methodology will be the application of IM-RAM sorbents for the highly selective analysis of small molecules [49] and the use of μ -SPE-columns [38,40,41].

Turbulent-flow chromatography has become a flexible high sensitivity system, which employs a 2D LC-MS/MS approach [19]. The turbulent-flow component is employed to concentrate the sample and to remove proteins and phospholipids [5]. The resulting extract is then separated on an analytical column, which provides enormous flexibility in terms of flow rate and column type. The analytical column is then linked to a suitable ionization technique for high sensitivity MS/MS analysis. A series of novel applications has appeared recently for the analysis of both drugs and endogenous metabolites, suggesting that this methodology could hold the key for future complex metabolomic applications [5]. A particularly attractive feature of the turbulent-flow 2D LC-MS/MS system is the ability to remove constituents from the biofluid that cause suppression or enhancement of ionization [69]. This makes it a realistic proposition to conduct analyses in the subpicogram range [70], which raises the possibility that turbulent-flow methodology can be employed in the future for the routine direct analysis of plasma and serum for low abundance endogenous metabolites such as vitamins and steroids [70,71]. Similarly, the recent application of 2D turbulent-flow LC-MS/MS to the analysis of tricyclic antidepressants in serum [72] suggests that this could be a very

useful technique in the future for the direct analysis of drugs and their metabolites in plasma and serum.

Recently, a novel system incorporating an automated direct analysis in real time (DART) ionization source coupled with a triple-quadrupole mass spectrometer was developed and evaluated for direct analysis of drugs in biofluids [73]. This system can potentially eliminate the need for sample cleanup and chromatographic separations. Additional pumping of the mass spectrometer ion source was employed to compensate for the increased vacuum load from the high flow helium introduced by the DART. This resulted in an improvement of detection sensitivity by a factor of 10- to 100-fold and minimized matrix effects on a diversified group of analytes. The system was employed for the direct analysis of biofluid samples with similar results to those obtained with conventional LC-MS/MS methods. Therefore, this new automated DART-triple quadrupole mass spectrometer system has significant potential future for high throughput direct biofluid analyses [73]. Finally, the μ -SPE-based RapidFire System might be a useful tool for high throughput MS quantitation of *in vivo* biofluid samples in situations where large sets of samples justify the up-front burden of method development [44]. Clearly, direct analysis of biofluid samples has come of age and is now a realistic alternative to more time-consuming off-line purification procedures particularly when large numbers of samples are involved.

17.1 SUMMARY

Present requirements to perform bioanalysis for submission to regulatory agencies have evolved as the result of bioanalytical workshops held in 1990, 2000, and 2006. Following the second meeting, the FDA issued its guidance in 2001. The European

Medicines Agency (EMA) has issued draft guidance, which will be issued as final guidance in February 2012.

Setting the assay range includes assessment of the lower limit of quantification (LLOQ), which is related to precision and accuracy of the lowest standard, as determined in replicate measurements, and is required to be within 20%. Chromatographic assays generally yield linear or quadratic response over a broad range of concentrations. Multiple days of validation data are needed to establish reproducibility of the regression model. The correlation coefficient of the standard curve must be >0.99 . When validating in multiple species, a mixture of full and partial validations is common. As each matrix is unique, full validations should be undertaken whenever the matrix is changed.

For regulatory bioanalysis, matrix of the standards must match study samples. Included with each analytical batch are blank matrix, a sample with only internal standard (IS), and a minimum of six nonzero calibration standards. The absolute difference between the back-calculated and nominal concentration for each calibration standard should be within 15% for all standards, except at the LLOQ where $\leq 20\%$ is acceptable. A minimum of 75% of the standards should be within these limits. Values falling outside these limits can be discarded, starting with the most deviant value and iteratively reregressing until all results are acceptable or the run fails. In cases where it is not possible to obtain the matrix in sufficient quantity to prepare standard and QC (quality control) samples, a surrogate matrix may be used. While it is preferable to have a certificate of analysis, some compounds available in very small amounts require only less qualification.

QC samples should be positioned evenly through the batch, reflecting the concentration of study samples. QC samples measured at a minimum of three concentrations in duplicate (or at least 5% of the unknown samples) are required. Spacing is within $3 \times \text{LLOQ}$, one near the center and one near the upper boundary (top quartile). Wider-range assays should include the addition of more QC levels to better represent study data. At least two-thirds overall and 50% at each level must be within 15% of their nominal value. When performing an assay validation, more replicates and additional QC samples are required to assess accuracy and precision at the LLOQ and to test dilutional linearity. A minimum of five determinations at each QC concentration are required. Additional QC samples include the LLOQ QC whose intraday and interday precision and accuracy needs to be within 20%. Dilution QC samples should test the maximum range over which the dilution is anticipated.

Matrix effect is the suppression or enhancement of ionization of analytes by components in the biological samples and is measured by comparing the response from a sample of blank matrix to which an equivalent amount of analyte was added after extraction to an equivalent amount in mobile phase. ISs in MS (mass spectrometry)-based assays can minimize the impact of matrix effects by normalizing response ratios. Having a highly variable matrix effect in individual subjects may cause irreproducibility. Absolute and IS-normalized matrix effects for six individual matrix lots are tested, and variability should be within 15%. When using stable isotope IS, this determination is unnecessary.

To accurately assess the recovery of analyte or IS from the sample matrix, response from an extracted sample is compared to a sample of blank matrix to which an equivalent amount of analyte was added after extraction. Apart from the criteria that recovery of analyte and IS be consistent, precise, and reproducible, there is no required minimum.

Carryover in an HPLC system is contamination by the preceding sample. If carryover is more than 20% LLOQ, its acceptance should be justified and appropriate precautions used to minimize its impact. In contrast to carryover, contamination is unpredictable and may occur during any part of the study (dosing, sample collection, or analysis).

Guidance does not mandate that within a study dilution QC samples are used, provided dilutions are conducted with like matrix and tested within validation. A preferable approach is to include dilution QC samples whenever study samples require it.

Procedures must evaluate the stability of analytes during sample collection and handling. The effect of different anticoagulants on stability should also be tested. Use of selective inhibitors is preferred since these can be added in smaller quantities and can result in minimum change to the matrix. Nonspecific binding of drug to containers also needs to be considered. In addition to stock solution stability, assessments in the unaltered matrix of qualifying QC samples include long-term stability under storage conditions, freeze–thaw cycles, bench-top (room temperature and/or ice processing), processed sample or extract stability, and reinjection integrity.

Specificity should ensure that background response from six independent lots of blank matrix is <20% of the response from the LLOQ sample and <5% of the IS. Selectivity is defined as “the ability of the bioanalytical method to measure and differentiate the analytes in the presence of components that may be expected to be present.” Guidance requires that “each blank sample should be tested for interference, and selectivity should be ensured at the LLOQ.” An assay should be tested whenever clinical studies are performed, where there is the potential for concomitant medication or when used in drug–drug interaction (DDI) studies.

Only qualified and properly maintained instruments should be used for drug analysis. To qualify instruments at time of use, a system suitability test may be used. This generally includes replicate testing of the analyte for sensitivity and precision near the LLOQ before starting an analytical run. Similar tests following the run may be used to confirm instrument stability.

A means to judge individual results, based on the response of ISs, is often used. Rules must be in place that allow *a priori* decisions to reject sample results that show aberrant IS response. Use of a stable label rather than a structural analog as IS is always preferable, as, once equilibrated within the matrix, it compensates for any changes.

Samples may be reanalyzed for an assignable cause such as a technical error, poor chromatography, unacceptable IS response, or evidence of carryover. The original result is discarded, and the sample is reanalyzed in singlet. The acceptable reanalysis value is reported. Samples may also be reanalyzed for anomalous results or for pharmacokinetic (PK) reasons. Typically, confirmatory reanalysis is performed in replicate and the original result is either confirmed or replaced.

There are a number of situations where the performance of QC samples may not adequately mimic that of study samples from dosed subjects (incurred samples). Recent studies have required the assessment of incurred sample reanalysis (ISR). Randomly selected subjects include a minimum of 10% of the total analyzed samples. For larger studies, 5% of the total sample size is allowed. The difference between the initial and reanalyzed values should be $\leq 20\%$ (small molecules) in at least 67% of reassayed samples. Unlike repeat analysis for anomalous results or for PK reasons, ISR is performed in singlet from selected samples about the $C_{\max}$ and in the elimination phase.

Simultaneously measuring multiple analytes increases the statistical probability of run failures. Results should not be rejected for the remaining analytes if one analyte

fails. Concentrations from the first accepted run should be reported. If this analyte is repeated in simultaneous assays when analyzing for different analytes, it is not necessary to quantitate the already reported analytes.

Tiered assays can be used when reference standards of metabolites are unavailable and a preliminary assessment of human exposure and safety coverage is needed. There are multiple strategies that have been used to allow this across-species comparison. Once the metabolism is fully known, a solid decision can be made regarding what regulated assay(s) would be effective in supporting later clinical drug development.

Assay transfer within a laboratory or across laboratories involves an assessment of its equivalence following the change. Depending on the nature of the change, this may involve either a partial or full validation. Conformance testing by analysis of QC samples is a good practice but not required. Cross-validation by testing study samples is unnecessary unless two different assays are used within a single study.

Proper installation and operational and performance qualification of all instruments is required before performing regulated bioanalysis. User specifications and a validation plan should be developed. System functionality can be verified and any gaps identified. User acceptance testing (UAT) should include a traceability matrix to regulations.

When unsure of clinical success, exploratory investigational new drug (eIND) studies allow the assessment of new chemical entities that have undergone limited safety testing. Provided there is a sensitive LC-MS (liquid chromatography-mass spectrometry) assay or a method such as AMS (accelerator mass spectrometry) is used, a subtherapeutic dose may afford the opportunity to quickly determine adsorption, distribution, metabolism, and excretion (ADME) properties.

Peptides, small proteins, and oligonucleotides are representative of mid-size molecules that can be directly measured using LC-MS. Larger proteins may be digested and indirectly measured by LC-MS analysis of a peptide surrogate. When using a mixture of ligand-binding and LC-MS assays, cross-validation using both QC and study samples can help to illustrate assay differences.

Dried blood spots (DBSs) offer numerous advantages, particularly from the in-life study. Bioanalytical challenges include recovering the analyte from filter paper without the introduction of matrix effects and overcoming sensitivity limitations for highly potent drugs. As more investigators explore the potential of DBSs in clinical studies, there will undoubtedly be regulatory bioanalytical guidance that comes forth.

The nature of regulated bioanalysis is ever changing. New methodology, technology, and novel drug candidates challenge past practices. Common procedures are now in place for validation and sample analysis of both large and small molecules. Drug development has integrated new cultures and perspectives into our science, making it essential that global regulatory requirements are standardized to allow for new drug submissions in all countries.

17.2 HISTORY OF REGULATED BIOANALYSIS

The term *bioanalysis* was derived in the 1970s to describe the quantification of drugs in biological fluids in support of PK studies. It evolved over the next decade to include toxicokinetics, the assessment of systemic exposures in animals undergoing toxicology studies. As many drug candidates show nonproportional dose–exposure relationships,

underpinning toxicity assessments with plasma or target-organ drug levels was a significant advance.

Problems related to preclinical research studies revealed serious issues with the conduct of safety studies submitted to the FDA. As a result, FDA published in December 1978 its good laboratory practices (GLP)s regulations. These regulations were collected in Title 21 “Food and Drugs” of the Code of Federal Regulations (CFR) as Part 58 “Good Laboratory Practice for Nonclinical Laboratory Studies” and applied to all non-clinical safety studies intended to support research permits or marketing authorizations of products regulated by FDA. For clinical *in vivo* bioavailability or bioequivalence study, 21 CFR 320.29 can be applied.

In Europe, adherence to GLPs is governed by the European Union (EU) law and, as in the United States, is applied to nonclinical safety testing. In 1981, the Organization for Economic Co-operation and Development (OECD) finalized its GLP principles. Later, the European Community adopted the OECD principles of GLP, requiring states to incorporate into their laws that nonclinical safety studies be conducted to GLP standards. ICH S3A provides limited bioanalytical guidance in the assessment of toxicokinetics, whereas ICH E6 requires documented competence in bioanalysis for clinical studies. EMEA CPMP/EWP/QWP/1401/98 states that the bioanalytical part of bioequivalence trials should be conducted according to GLP principles.

Although clinical bioanalysis is generally performed to the same high standard as nonclinical bioanalysis, it cannot be considered GLP. Methods are validated to the same standards, and there is adherence to many parts of the quality system that are fundamental to GLP regulations. The European Bioanalytical Forum has promoted the use of “regulated bioanalysis” to encompass studies that adhere to common regulatory guidance for bioanalysis rather than “GLP bioanalysis.” Both terms will be found within the literature.

Present US requirements to perform bioanalysis for submission to regulatory agencies have evolved over the last two decades. Karnes *et al.* [1] provided early bioanalytical guidance. Shah *et al.* [2] published the conference report from the first bioanalytical method workshop. This report served as the foundation for bioanalysis for several years. The workshop defined accuracy, precision, selectivity, sensitivity, reproducibility, limit of quantification, stability, and recovery. Of these, the assessment of accuracy and precision was one of the most criticized parameters [3,4]. Statistical assessments from larger data sets were proposed as an alternative to fixed acceptance rules [5]. These arguments also found favor within the large-molecule bioanalysis community where less precise and accurate immunoassays had difficulty meeting rigid requirements. However, having simple, *a priori* rules by which to judge an assay validation and its application was welcomed by those performing small-molecule bioanalysis and was readily adopted.

During this period, two other guidance documents emerged from the International Conference on Harmonization (ICH), which were approved by the EU, the United States, and Japan [6,7]. While both dealt with analytical methods for pharmaceutical products, they nonetheless provided guidance on method validation. Because the workshop report was not an official document, the FDA decided that a guidance should be developed. The draft guidance was issued in January 1999. The second bioanalytical method workshop was held in January 2000 and reported later that year [8]. In 2001, the FDA issued its final guidance on bioanalytical method validation [9]. This guidance has served the small-molecule bioanalysis community for many years.

The large-molecule (biologics) community worked from separate guidance [10,11]. It was not until the third bioanalytical method workshop in 2006 that both the small- and large-molecule communities accepted similar rules for method validation and sample analysis. Both assess accuracy and precision in a similar manner; however, acceptance criteria differ. For large molecules, accuracy and precision were both required to be within 20% or 25% at the LLOQ, whereas the small-molecule community continued to require 15% (20% at LLOQ). Having both small- and large-molecule groups define common procedures and similar acceptance criteria allowed easier assessment of data by regulatory agencies.

The third bioanalytical workshop report was issued in 2007 [12]. Apart from the inclusion of the ligand binding or large-molecule bioanalysis into a common community, the most notable change was the requirement to demonstrate repeatability from incurred (study) samples. This had been a requirement of the Health Protection Branch for Canadian submissions from 1992 until the Therapeutics Products Directorate of Health Canada revoked the policy in 2003. Under this Canadian requirement, 15% of samples were randomly selected and reanalyzed.

Since 2007, ISR has become common practice for US submissions, which has added value by uncovering errors unnoticed from QC samples [13]. Other additions included an assessment of matrix effects [14] and carryover, as well as clarifications on stability testing and use of system suitability samples. More details on documentation were also added in the conference report, aiding in transparency and giving guidance on reporting failed runs.

Overall, there were limited changes to the prior procedures and acceptance criteria for small-molecule bioanalysis. There were significant changes for ligand-binding assays of large molecules. The report recognized the inherent differences in drug product manufactured from a biological process from drug substance generated by chemical synthesis. The heterogeneity of a biologic product, often including posttranslational glycosylation or phosphorylation, requires special consideration when defining validation criteria. Ligand-binding assays are often necessary to define not just chemical stability but the biological integrity in a stability assessment. In contrast, chemical stability of small molecules is more easily determined. Reagents, especially antibodies, used in ligand-binding assays may vary more than chemicals used in small-molecule assays. For these reasons, acceptance criteria were lessened. Assessment of total error (sum of the absolute value of mean bias and precision) was required to be within 30% (40% at LLOQ). No similar requirement of total error exists for small-molecule guidance.

The EMEA issued draft guidance on the validation of bioanalytical methods in September 2009, and requests for comments ended May 2010 [15]. Within it, many of the procedures and acceptance criteria within the FDA guidance and bioanalytical method workshop reports have been adopted. However, there are some notable differences. The EMEA guidance goes further in defining when the possibility of back-conversion of metabolites to parent should be tested. More detailed procedures on assessment of the matrix effect, particularly with regard to population diversity, have also been recommended. Inclusion of testing lipemic and hemolyzed plasma in the EMEA draft guidance parallels that found within the Brazilian regulations [16]. As a result of divergence from a commonly accepted FDA guidance, pharmaceutical companies are requesting that a common standard be adopted for global regulatory submissions [17,18]. Even minor differences in procedures or acceptance criteria could make a submission unsuitable in some countries. Therefore, establishing common

global expectations for method validation and sample analysis is critical to global submissions.

This chapter discusses regulatory bioanalytical requirements in a manner that attempts to provide guidance on how to achieve acceptance criteria. Deploying assays without fully characterizing their limits can result in failure runs. This is most apparent when assays are transferred to new laboratories or are used by new analysts. Best practices often include a standardized design and testing of assays during method development to better ensure that they are relatively insensitive to small changes. Knowing critical limits helps to hold an assay in control or provides the information needed to quickly diagnose and correct failures. We focus on the use of LC-MS, particularly in combination with mass spectrometry/mass spectrometry (MS/MS), to measure drug molecules and their metabolites to regulatory standards.

17.3 RESPONSE CALIBRATION

Sensitivity is defined as *the slope of the calibration model*. It should not be confused with the ability to detect or quantify an analyte in a given matrix. The limit of detection (LOD) is related to the signal-to-noise (S/N) ratio and, at a minimum, is required to be ≥ 3 . The exact assessment may vary dependent on whether peak-to-peak or root mean squared (RMS) noise is used. The LOD is rarely used in the field of bioanalysis, except that chromatographic peaks of standards must have a signal that is fivefold greater than the background [9]. Some have proposed that the LLOQ should require a S/N ratio of ≥ 10 . This is good guidance, as it is unlikely that all samples will be as free from interference as those analyzed during the validation. The LLOQ is related to precision and accuracy of the lowest standard, as determined in replicate measurements, and is required to be within 20%.

Having an understanding of what limits quantification at the extremes of the standard curve can guide method development and allow proper decision on assay range. In an ideal situation, detector response is proportional to concentration over a wide range. Provided there are limited losses due to adsorption (nonspecific binding), testing the assay range using pure solutions can establish the optimum detection range. Under these conditions, there are no recovery, stability, or matrix effects that can either dilute analyte concentration or its response. For a pure solution near the LLOQ, electronic noise limits detection. A major objective of method development should be the extraction and separation of drug from plasma to yield response limited by ion formation, transmission, and detection. Release of adsorbed analyte from a prior injection (injector carryover) can result in greater than the proportional response at low levels, so attention should be paid to the normalized response (response factors) to make a proper assessment. Near the upper limit of quantification (ULOQ), ionization and detector saturation can result in lower than the proportional response. MS systems using pulse counting electronics may also suffer from the inability to discriminate multiple ion events within the detection time frame. Within a 10-ns counting window, ion events $> 10^8$ counts per second result in detector saturation. Analog electron multipliers do not suffer from this problem but are more limited by electronic noise at the LLOQ. With present instrumentation, ionization saturation generally occurs before detector saturation. This is typical for electrospray ionization (ESI) and is discussed later in

greater detail. Unless limited by adsorption, the assay range will be no greater when the analyte is placed into the matrix than when it is in a pure solution.

When spiked into matrix, chemical background often interferes with detection near the LLOQ. Less obvious background such as phospholipids in plasma, bile acids in bile, and salts or urinary acids in urine can modulate MS detection and are referred to as *matrix effects* [14]. Both chemical background and matrix effects can significantly impact measurements at low levels. While it may be easy to detect analyte at low levels, precise and accurate quantification is more difficult. When coeluted with analyte, the numerous and abundant components within biological fluids and tissues, compete for ionization with the analyte and affect response. If they vary significantly from the matrix used to prepare the standard curve, there is the potential for error. Use of a stable label as an IS compensates for variation in matrix effects and is a good addition to any assay. For multiplex assays, obtaining multiple stable label ISs can be difficult. Caution should be used when measuring parent drug and metabolites with only stable label IS of parent drug. High levels of parent drug can suppress ionization of its stable label IS, which, if also used to measure metabolites, can result in errors.

Unlike immunoassays, chromatographic assays generally yield linear or quadratic response over a broad range of concentrations. Method development should strive to establish the simplest fit, a linear fit with minimum weighting. Validation should strive to establish the best and most reproducible fit. The regression model must be justified and shown to be reproducible. Justification involves testing multiple regression models and different fitting parameters. These tests should use validated software applications, including the MS or LIMS (laboratory information management system) software, which will perform the sample analysis.

Linear fits are common; however, quadratic models can be used. A quadratic regression model can be used to address less than proportional response at increasing concentrations due to ionization or detector saturation. When using quadratic curves, a stable label IS is highly recommended to overcome intersample variations and their potential impact on MS response at its ionization limit. By using a stable label IS, the response ratio is better normalized, resulting in an extended dynamic range. Less than proportional response at decreasing concentration is often due to adsorption losses and associated changes in extraction recovery. This is common for hydrophobic drugs in matrices such as cerebral spinal fluid (CSF) and urine. Quadratic fitting should not be used to correct for nonlinear response at lower concentrations. Less than proportional response at low concentrations should be corrected by selecting a different container, adjusting pH to enhance solubility, or adding a solubilizing agent such as a surfactant or organic diluent. In both extremes, sensitivity is decreased as either the recovery near the LLOQ or detection at the ULOQ is impacted.

A much preferred approach is to require linear fitting of calibration curves. Linear fits can restrict the dynamic range that may require more dilution of study samples. However, a linear response model generally has better interday reproducibility. A linear fit is therefore the preferred and the anticipated response function. Deviations from a linear regression model may be challenged, particularly when fitting parameters show significant interday variations.

Weighting ($1/x$ or $1/x^2$) should be used for heteroscedastic data or whenever error is proportional to sample concentration. These corrections should be carefully scrutinized as daily changes in carryover or contamination can impact whether $1/x$ or $1/x^2$

weighting should be used. The power for weights approach evaluates the linear dependence of the logarithm of the standard deviations of peak response on the logarithm of sample concentration [19]. Other statistical approaches can also afford an unbiased selection.

Guidance requires the correlation coefficient (r^2) to be >0.99 . It is likely that many regression models will meet the guidance criteria. Examining residual errors from validation data can aid in selecting the best fit. Proper documentation of the rationale for selecting the model is critical. Multiple days of validation data are needed to establish reproducibility of the regression model.

A common mistake is to define a linear model during validation only to find, following an improvement in instrument performance, that a quadratic fit may have been better. It is possible to inject less extract or simply retune MS performance to its less sensitive, linear state. However, if a wide assay range was needed, a quadratic fit may have been a better fit. When sensitivity is decreased, a quadratic fit is reduced to a linear fit (quadratic term $\rightarrow 0$). The reverse is not possible. Linear fits are preferred and can yield assays with reasonable dynamic range, provided extract purity and separation avoids ionization saturation. It should be noted that during the establishment of the regression model, variables, including injection volume, should be controlled. It is the total amount of coeluting components that affect MS response, so changes in their absolute amount will affect ionization saturation [20].

When validating in multiple species, a mixture of full and partial validations is common. Many analysts perform full (three days or more) validations in man and the primary (rodent and nonrodent) toxicology species with partial (one day or more) validations in other species. For instance, plasma assays in rat and either dog or monkey used for long-term (definitive) toxicology studies would receive full validation. Plasma assays for mouse (carcinogenicity or pharmacology), rabbit (reproductive), and dog (safety pharmacology; if monkey is used as primary) may be performed as partial validations. Others perform full validations in all species. Unless there is a reason to suspect a gender, or population difference, validations in humans generally assume equivalence. In contrast, validations in animals are generally both species and strain-specific. Testing any differences can be performed within the full validation to demonstrate equivalence on substitution. Changes in sample anticoagulant are not assumed to be equivalent and require at least a partial validation.

Provided there are no significant differences across species, the assay range established from the full validations should be applicable to other species. This simple assumption fails when there are significant interspecies differences in sample volume, drug potency, PK properties, stability, recovery, matrix effects, and endogenous interference. It is, however, preferred to test assay applicability across species before undertaking formal validations. Having a common analytical procedure reduces complexity in drug development. Much can also be learned from discovery studies, as assays were generally applied to numerous species and matrices.

Quantification of multiple analytes (comedications, metabolites) across species multiplies challenges in defining the proper assay ranges and regression models. Species differences in metabolism are common, resulting in different ranges and regression models for parent and metabolite. Multiple component assays should therefore be undertaken with great care to avoid deploying an assay with high failure rates. Some sense of assay requirements in each species can generally be gained by reviewing prior discovery studies, and this is helpful in devising a common analytical strategy.

The analyst's ability to control both contamination and carryover will also affect decisions on the LLOQ and assay range. Bioanalytical guidance restricts contamination of blank samples to within 20% of the LLOQ. EMEA also has guidance on measuring drug levels in control animals from toxicology studies [21]. Since the bioanalyst's role is to define whether control animals were contaminated, careful consideration of the LLOQ should be made to avoid false-positive detection and quantification. Contamination, held in control by more experienced analysts, may be increased when less experienced analysts undertake the analysis. Automation and proper training serve to reduce this risk.

The regulatory expectation is that assay range should be adjusted to study needs. It is common to have a high sensitivity, wide range assay during first-in-human studies. By the end of the multiple ascending dose (MAD) study, some indication of a safe, therapeutic dose should have been established. The analyst may therefore wish, at this time, to consider whether the assay range should be adjusted. Apart from being inefficient, dilution of study samples can amplify errors. This practice is more common to highly sensitive, narrow range immunoassays. However, dilution factors as great as 1000-fold have been used when measuring wide therapeutic margin drugs in high dose toxicology studies by LC-MS. QC samples must reflect study samples, so readjusting the range or adding extra QC samples may be needed.

As each matrix is unique, full validations should be undertaken whenever the matrix is changed. When urine data is critical to interpret PK or safety data, a full validation is needed and measurements may be required in all samples. For instance, in cases of compounds that show moderate-to-high renal clearance or where the kidney is the target site of action or toxicity, an assay should be fully validated in urine and a routine urine analysis may be required. Full validations are less needed to make early clinical assessments, particularly when animal studies show little parent drug is excreted in urine. Estimating urine levels at the highest single dose before deciding on the urine assay range for multiple dose studies is one means to better judge its requirements before validation. In either case, sufficient testing must ensure that sample collection avoids losses due to instability or irreversible adsorption. Measuring renal clearance and testing its dose proportionality at steady state is generally an objective that will require a validated assay. Most would accomplish this objective within the MAD study.

There is less guidance when demonstrating penetration into remote compartments. When critical to understanding PK–PD (pharmacodynamics) relationships, a full validation should be undertaken. For instance, measuring levels in synovial fluid for arthritis [22], bone for osteoporosis [23], CSF for CNS [24], or tumor for oncology [25], drugs would support target engagement. Tissue analysis is common in discovery to ensure penetration at the site of action, but translation to human studies can be difficult. There are many practical limitations, including obtaining tissue or bone samples, finding sources or surrogates for these matrices, assessing consistency in recovery of standards versus study samples, and ensuring the proper preparation of homogenates. Within toxicology studies, staff is often skilled and can prepare homogenates for storage before shipment and bioanalysis. Storing homogenates rather than tissue allows one to conduct a proper stability campaign. In contrast, preparing homogenates at multiple clinical sites is a challenge. These objectives should be supported using a full validation.

If one wants to demonstrate penetration to numerous clinical tissues but in a limited numbers of samples, a partial validation is generally acceptable. This would be the

case of an antibiotic tissue distribution study to determine whether numerous nonsystemic levels exceeded drug potency throughout the dosing interval (e.g., $C_{\text{tissue}} > IC_{50}$). A similar penetration assessment of antiviral agents measures their intracellular drug levels in peripheral blood mononuclear cells (PBMCs). Intracellular determinations afford a better understanding of drug uptake, efflux, and intracellular metabolism [26,27]. Since only a single matrix is involved and there are no limitations on its availability, a full validation would be expected.

17.3.1 Standards

For regulatory bioanalysis, standards must match study samples, which are most frequently plasma, blood, or urine. It is unacceptable to quantify study samples using another matrix standard curve. It is acceptable to dilute study samples within another matrix, provided standards are prepared in an identical manner. This may aid quantification by using a mixed calibrator curve or by diluting samples in a less problematic matrix.

Included with each analytical batch are blank matrix (sample without IS), zero standard (sample with IS), and a minimum of six nonzero calibration standards. The absolute difference between the back-calculated concentration and nominal concentration of each calibration standard should be within 15% for all standards, except at the LLOQ where $\leq 20\%$ is acceptable. A minimum of 75% of the standards should be within these limits. Values falling outside these limits can be discarded, starting with the most deviant value and iteratively regressing until all results are acceptable or the run fails. When performing sample analysis, the exclusion of calibration standards cannot change the established model.

One standard curve is acceptable. Some prefer to use a second curve, often placing one at the front and the other at the end of the run. A significant change in sensitivity over the course of the run or a mistake in preparation will be noted by this approach. All results must be integrated into a common standard curve. Runs where the sensitivity changes over the course of the run by more than 25% will generally fail to match standards with QC samples.

It may not be possible to obtain the matrix in sufficient quantity to prepare standard and QC samples. In these instances, a surrogate matrix may be necessary. This is often the case in pediatric or human penetration studies. If unavailable, artificial CSF may serve as surrogate matrix for human CSF. Likewise, the same animal tissue from a closely related species may serve as a surrogate for human. A partial test of equivalence is always needed. Using predose or control matrix to prepare standard and QC samples is sometimes possible. Dilution using a more common matrix also helps to reduce the need for large quantities of matrix.

Although it is preferable to have a certificate of analysis for all analytes, some compounds are available in very small amounts, with less qualification. Since the issuance of the Metabolites In Safety Testing (MIST) guidance [28], the sourcing and qualification of metabolite reference standards has become increasingly important. More on this topic is presented later. Guidance requires that reference standards come from the USP (United States Pharmacopeia) compendial standards, a reputable commercial source, or are custom synthesized and qualified by an analytical laboratory or other noncommercial establishments [9]. Source and lot number, expiration date, certificates of analyses (if available), and evidence of identity and purity must be furnished.

Biosynthetic or isolated metabolites yield quantities that are insufficient to be as well characterized as synthetic reference materials. One approach isolates microgram levels of individual metabolites for identification using MS and NMR, with quantification using NMR [29,30]. NMR signal response is independent of structure, allowing isolated metabolites to be quantified by comparing their response to that of a known added amount of parent drug. In another approach, radiochemical detection has been used to calibrate stock solutions of metabolites [31]. This approach requires separation of metabolites, as, unlike NMR or MS, detection is nonspecific. Detector response serves to calibrate the concentration of each metabolite by the response to parent drug. The bioanalytical standard curve is prepared by spiking the isolate into the matrix with subsequent dilution. The value of radiochemical detection is that metabolites do not need to be isolated or identified before their quantification. However, radiolabeled drug is needed. For measurements in humans, the metabolite also must be seen in animals or from human *in vitro* experiments. Neither approach requires time-intensive synthesis. However, without synthesis, there is no confirmation of the assigned structure or supply for testing of activity or toxicity. Bioanalytical and biotransformation scientists need to carefully decide how to undertake metabolite quantification to properly integrate approaches with clinical ADME studies.

When measuring endogenous compounds such as biomarkers, the use of a surrogate analyte may be required. Removing endogenous levels by charcoal stripping can be ineffective [32]. Likewise, antibodies may be unavailable for immunoprecipitation. Addition of a stable label analog can serve as a surrogate calibrator. For instance, a tris ^{13}C stable isotope is measured for standard and QC samples. The unlabeled isotope is measured in study samples. To avoid primary kinetic isotope effects, use of a ^{13}C or ^{15}N stable label is preferred. If a ^2H stable label is used as a surrogate analyte, its response must be demonstrated to be equivalent to its nondeuterated form.

Another variation of the surrogate analyte approach is when a peptide digestion product is measured as a surrogate for a protein. Protein is indirectly determined by measuring a representative peptide following enzymatic digestion. In one example, matrix metalloproteinase-9 (MMP-9) was determined in mouse serum by capturing on magnetic beads coated with MMP-9 antibody, trypsin digestion, and LC-MS/MS analysis of the surrogate peptide GSPLQGPFILTAR [33]. Assessment of sequence specificity of the selected fragment was aided from database searching. Stable label of the peptide can serve as IS, and pure peptide is used as reference standard. Highly accurate peptide assays can be established. However, consistent capture and conversion of the protein to its surrogate peptide is needed for accurate analysis of protein. Any variation in recovery or conversion of a study sample from the standards will result in errors. Addition of IS following immunoprecipitation and enzyme digestion only serves to compensate for variations in the LC-MS analysis. Similar concerns are present when assaying antibody–drug conjugates (ADCs) for total drug [34]. A more accurate, but less feasible, approach is to incorporate stable label protein before isolation and digestion.

17.3.2 Quality Controls

QC samples should be positioned evenly through the batch, reflecting the concentration of study samples. When study data fall over a small percentage of the calibration curve, none of the QC concentrations may be near the unknown concentrations, limiting the

monitoring power of the QC samples. Adjustment of either the assay range or QC number and placement is expected.

QC samples are measured at a minimum of three concentrations in duplicate (or at least 5% of the unknown samples) are required. Spacing is within $3 \times$ LLOQ, one near the center and one near the upper boundary (top quartile). Grouping “near the center” or “midrange of the calibration curve” has afforded some latitude in mid-QC placement. Some have moved from its linear (50% of ULOQ) placement closer to a logarithmic (geometric mean) placement. This is consistent with a desire to more accurately capture the elimination phase. Depending on interpretation, there are significant differences. Table 17.1 illustrates the disproportionate gaps between QC samples when a linear placement is used instead of a geometric mean. When calculating the mid-QC, adjustment of its final concentration should be done to allow for easy preparation of this QC. Another option is to include two mid-QC samples. This has the added value of providing better coverage when study samples differ from their expected concentrations. Wider-range assays (≥ 1000 -fold) should include the addition of more QC levels to better represent study data.

During sample analysis, each batch should contain at least six (minimum 5% of total) QC samples. QC samples at a minimum of three concentrations in duplicate are added to each plate. At least two-thirds overall and 50% at each level must be within 15% of their nominal value. It is advantageous to avoid odd replicates, as at least two of three QC samples would be required to meet the 50% rule.

The analyst should make every effort to minimize the amount of organic spiking solution and to match QC and standard preparation. Study samples contain no organic solution. Even a few percent of an organic solution can denature proteins, causing a loss in enzyme activity or protein binding. The result is an inaccurate assessment of stability. Deactivation yields a false stability not seen with incurred samples. Apparent instability due to analyte entrapment within precipitating plasma proteins or instability when analyte is released from protecting proteins can also occur. Preparation by serial dilution in matrix is one effective means to reduce the organic composition in QC samples.

When performing an assay validation, more replicates and additional QC samples are required to assess accuracy and precision at the LLOQ and to test dilutional linearity.

TABLE 17.1 Dynamic Range and its Associated Gap Between QC Samples Using Either Linear (Top) or Geometric Mean (Bottom) QC Placement of Middle QC

Range	Low	Mid	High	Fold Gap (Low–Mid)	Fold Gap (Mid–High)
<i>Linear Mid-QC</i>					
100	3	20	80	5.7	3.0
250	3	50	200	15.7	3.0
500	3	100	400	32.3	3.0
1000	3	200	800	65.7	3.0
<i>GM Mid-QC^a</i>					
100	3	15.5	80	4.2	4.2
250	3	24.5	200	7.2	7.2
500	3	34.6	400	10.5	10.5
1000	3	49.0	800	15.3	15.3

Abbreviation: GM, geometric mean.

^aSquare root (low QC $\times$ high QC).

A minimum of five determinations at each QC concentration are required. In practice, many laboratories use replicates of six to better align with acceptance criteria. Additional QC samples include the LLOQ QC whose intraday and interday precision and accuracy needs to be within 20%. Dilution QC samples should test the maximum range over which the dilution is anticipated. If proven during validation, dilution QC samples do not need to be run in study sample analysis. This approach tests only dilutional linearity of the assay. It does not provide routine monitoring of the analyst's ability to execute dilutions nor does it test the ability to dilute matrix from different subjects (parallelism). For that reason, many include dilution QC samples within runs to support values reported for any diluted samples. However, neither LLOQ nor dilution QC samples need to be included within regular analytical runs.

While up to 25% of standards not meeting acceptance criteria are deactivated, QC samples should never be removed unless there was an assignable analytical cause. Measurement of the intrarun and interrune assay precision and accuracy during both validation and study sample analysis requires the entire population of QC data. Outlier tests such as Dixon's or Grubbs' [35] test may be applied, but they should be judiciously used.

QC samples are considered as a surrogate for study samples in which the true (nominal) concentration is known. Testing of incurred (study) samples reflects the observation that QC samples do not always behave the same as study samples. Some causes for this observation are discussed later. While replicate analysis of incurred samples tests interday precision, QC samples generally provide the only assessment of accuracy. Additional means to derive a true result from an incurred sample include measurements at multiple dilutions (tests parallelism) and the method of standard addition. Both require multiple aliquots of sample, are time intensive, and would need validation. For these reasons, they are not generally used. Validation establishes precision using QC samples selected by the bioanalyst, whereas ISR tests interday assay variability from the study population.

17.4 MATRIX EFFECTS

Nonselective detection of analyte signal, resulting in the apparent elevation of its true concentration, is referred to as *background* or *chemical noise*. Components within the chemical matrix can also either reduce or elevate the apparent analyte concentration by affecting detector response. The matrix effect is therefore the suppression or enhancement of ionization of analytes by matrix components in the biological samples [36]. A quantitative measure is the matrix factor (MF), which is the ratio of the analyte peak response in the presence of matrix ions to its response in the absence of matrix ions (Table 17.2). Spiking analyte into extracted blank matrix and comparing its response to an equivalent amount of pure compound is the best means to quantitatively assess this parameter [37]. The MFs of both the analyte and ISs should be determined. The relative MF is the ratio of the two and should be near 1.0.

Matrix effects are generally due to components within the sample, which are at high abundance, and yield high response. Salts or urinary acids are abundant and ionize readily in ESI, affecting analyte response in urine assays. Urinary salts or acids can also entrap drug during precipitation, so making the proper assessment is important. The high abundance, good surface properties, and ionic nature of phospholipids make them

TABLE 17.2 Determining Matrix Factor and Recovery (Extraction Efficiency)

Analyte	Internal Standard
Preextraction spike	Preextraction spike
Postextraction spike to blank	Postextraction spike to blank
Mobile phase spike	Mobile phase spike
Recovery (analyte or IS) = (preextraction spike/postextraction spike) $\times$ 100%	
Matrix factor (analyte or IS) = (postextraction spike/mobile phase spike)	

a concern in plasma assays [38,39]. Bile acids, present at millimolar concentrations in bile, can impact analyte ionization. The levels of bile acids in urine or plasma are far less and therefore not generally a problem in these matrices. Each matrix and each ionization method has its unique challenges, requiring sufficient extraction or chromatographic separation before ionization.

Ionization that occurs concurrently with desorption from a condensed phase is generally more prone to matrix effects [40]. ESI has shown greater matrix effects than atmospheric pressure chemical ionization (APCI) or atmospheric pressure photoionization (APPI). The requirement to volatilize analyte before either ionization within a corona discharge (APCI) or photoionization (APPI) source effectively removes many matrix components that impact analyte ionization [41,42]. Phospholipids are not volatile and therefore do not present the same problems in APCI or APPI as they do in ESI. However, many analytes are not volatile and require ESI with proper sample processing before ionization.

Indirect detection of matrix effects by postcolumn infusion is relatively insensitive and does not identify the offending component within the matrix [36]. Having a direct and simple means to identify exact phospholipids in plasma greatly assists their monitoring and removal [43]. Positive precursor ion scan of m/z 184, positive neutral loss (NL) scan of 141 Da, and negative precursor ion scan of m/z 153 are the three widely used means. When a total assessment of phosphatidylcholines is desired, monitoring the m/z 184 $\rightarrow$ 184 transition under high source energy is most commonly used [39].

ISs in MS-based assays can minimize the impact of matrix effects by normalizing response ratios. Matrix effects observed for stable isotope labeled IS are similar to those observed for the analyte, particularly for ^{13}C or ^{15}N and less so for ^2H stable label analogs. From a practical perspective, deuterated ISs are generally more readily available and some can be prepared using single step alkylation or hydrogenation reactions. Deuterated stable labels can exhibit primary kinetic isotope effects not seen with ^{13}C or ^{15}N stable labels. They are generally acceptable, provided the label is not scrambled during MS analysis and is metabolically stable within the matrix. The introduction of higher resolution separations (e.g., UPLC (ultraperformance liquid chromatography)) and more extensive substitution can result in uncompensated matrix effects if analyte and IS elute at different times. For these reasons, some have suggested coelution is always preferred, including when using a structural analog [44].

Matrix effects are less a problem when the matrix of the study population matches that used to prepare standard and QC samples. If the analyte response is affected in study samples, it should be similarly affected in standard and QC samples. Detection sensitivity can be affected but accurate quantification would not be. That premise is

generally true for animal studies, in which strains of similar genetic and environmental background are tested.

Matrix effect measures response from a sample of blank matrix to which an equivalent amount of analyte was added after extraction (postextraction spike) to response from a sample that contains the same amount in mobile phase (no matrix). Having a highly variable MF in individual subjects would be a cause for the lack of reproducibility of analysis. It is therefore required that the absolute MF and IS-normalized MF for six individual lots of the matrix be tested and that the variability in MFs, as measured by the coefficient of variation (CV), be within 15%. However, when using stable isotope IS, it is not necessary to determine the MF in six different lots.

To test assay specificity, Brazilian requirements define that samples of the biological matrix must be analyzed from at least one lipemic and one hemolyzed sample [16]. Blank samples must be tested using the established procedure and results compared with those obtained from the aqueous solution of the analyte, in concentration close to the LLOQ. A similar assessment within the EMEA guidance requires measuring MF in QC samples prepared from both lipemic and hemolyzed plasma [15]. This assessment will test the potential for phospholipid suppression at its extreme.

17.5 RECOVERY

The introduction of requirements to test sample diversity during method development and validation is good assurance that methods either will be entirely insensitive to population variability or will define their failure points. Brazilian guidance also requires that at least one hemolyzed sample be tested for specificity in a manner similar to that noted above [16]. While spectral interference from hemolyzed red blood cells (RBCs) is common in colorimetric assays used in clinical chemistry, the specificity of LC-MS assays makes them less prone to this problem. There are cases, however, when an extensively hemolyzed sample measured using LC-MS will be affected. The cause may include instability following the release of RBC enzymes, lower recovery from cell debris, or matrix effects from RBC components. The EMEA guidance requires measuring MF in at least one low QC sample prepared from hemolyzed plasma [15]. Testing extensively hemolyzed plasma assures one that lysed blood cells or their intracellular contents do not impact analyte stability, recovery, or detection. If the assay is sensitive to hemolysis, knowing its limits would allow one to make assessments of whether data should be reported [45,46]. Since most samples are not measured for hemolysis, attention to sample conditions and good documentation is needed.

Having an assay that meets global (FDA/US, EMEA/Europe, ANVISA/Brazil, TGA/Australia, SFDA/China, and MHLW/Japan) requirements is essential to support the registration of new drug candidates in all countries. Some of the less common requirements are associated with how matrix effect and recovery are assessed. There is an extensive effort among the bioanalytical communities to ensure that common standards are adopted. Included in this effort are the Global Bioanalysis Consortium, European Bioanalysis Forum, and Global Contract Research Organization Council for Bioanalysis. Large challenges lie ahead to achieve the right balance of consensus and the appropriate level of detail in the upcoming EMEA and FDA Guidance.

To accurately assess the recovery (extraction efficiency) of analyte or IS from the sample matrix using MS, matrix effects must be eliminated. This is achieved by

comparing response from an extracted sample to a sample of blank matrix to which an equivalent amount of analyte was added after extraction (Table 17.2). Use of a postextracted spiked sample corrects for matrix effects. Low, mid, and high QC levels need to be tested for recovery. Apart from the criteria that recovery should be consistent (independent of concentration), precise and reproducible for both the analyte and IS, there is no required minimum. Higher recovery is better, as even small changes in a low recovery assay can have great impact. Some laboratories do require a minimum by standard operating procedure (SOP).

The use of a postextraction spike works well for off-line extraction, but what about on-line methods such as turbulent flow [47]? When matrix is directly injected onto an on-line extraction with subsequent LC-MS analysis, an isolated extract is not obtained. In this case, the extraction recovery is presumed to be quantitative. To comply with the draft EMEA guidance, interbatch variability in response should be assessed by analyzing at least six batches of matrix in triplicate and achieving an overall CV within 15% [15].

Provided a close structural analog has been chosen as the IS, comparable recovery should be seen. Indeed, this should be one of the many defining criteria used in selecting an appropriate IS. Whenever possible, a stable label is preferred. Even still, it is important to ensure that the IS is properly equilibrated with the analyte in the matrix before beginning extraction. High affinity binding to matrix components can be difficult to disrupt. For instance, 2 mM of a competitive displacer was incubated for 2 h at 37°C to fully displace nanomolar levels of roxifiban from platelets [48]. Even the use of a stable label will not compensate for a procedure that improperly equilibrates IS before extraction.

Achieving consistent recovery from plasma or serum is less problematic than when one is working with blood, cells, tissues, or hard matrices such as bone. Partitioning between blood cells and plasma is important to measure for two reasons. First, it may determine the choice of matrix, blood, instead of plasma. Second, time-dependent partitioning is possible, so differences in the harvesting of plasma will impact PK. Similarly, slow release of analyte from tissue homogenates can complicate analyses. Proper introduction and equilibration of IS before extraction is needed to overcome differential recovery [49]. Recovery from study samples that have undergone different periods of equilibration should be tested. Slow equilibration of IS with analyte in the matrix may require a longer equilibration time, more vigorous mixing, or the addition of acid or a competitive displacer to overcome high affinity binding. Matrices such as bone require complete digestion before analysis [23]. Matrices that are more complex and difficult to homogenize will always present challenges to prepare standard and QC samples that mimic study samples. For complex cases, dosing radiolabeled drug and assessing recovery from study samples is an alternative approach.

Through-LC recovery, which for absorptive compounds can be greatly reduced at lower concentrations, is generally not tested or known. When low level adsorption is seen, the standard curve may have decreased sensitivity at lower levels than that seen from upper standards. Using high levels of an appropriate IS may compensate by masking active surfaces and exhibiting similar recovery at lower levels. It is more appropriate to select a better stationary or mobile phase that overcomes these low level losses. Peak tailing and varying background are often associated with reduced through-LC recovery at low concentrations. Both symptoms illustrate a propensity for high affinity binding to the injector or stationary phase. Including additives to the

mobile phase can overcome losses, but it must be done with care to avoid affecting MS response. The lack of understanding and correcting through-LC recovery problems can result in sensitivity changes during the run, poor apparent detection sensitivity, and variability in the chromatographic baseline. It is one reason why an extensive number of conditioning samples may be needed in an assay.

17.6 CARRYOVER

Carryover in an HPLC system is contamination by the preceding sample. It is generally predictable and quantifiable by examination of the method, allowing an accurate assessment of its impact. Method development should define the individual sources (e.g., liquid handler vs HPLC) so that its causes can be eliminated or reduced. Method validation should accurately measure carryover to define its expected contribution when samples are assayed. Relative carryover is measured by injecting the following sequence, blank-ULOQ-blank. An acceptable result is when the difference of the blanks is $\leq 20\%$ LLOQ. If carryover is more than 20% LLOQ, its acceptance should be justified and appropriate precautions used to minimize its impact.

A direct, yet inconvenient correction is to restrict the dynamic range of the assay. Precautions include the proper placement of samples to minimize changes in concentration and protection of samples with washout blanks. Even still, the influence of carryover is unknown when the preceding sample is above the limit of quantification (ALQ). It is not until the ALQ sample is reassayed that an assessment can be made. Concentration-dependent carryover can complicate this assessment. Saturation of non-specific binding sites causes concentration-dependent carryover and is most evident when a larger relative carryover is seen on subsequent injections (delayed washout). One can implement procedures that recognize high carryover within a run and *a priori* rules to reject individual samples or batches [50]. If not reduced and uncontrolled, one should be prepared to fail individual results or runs, intersperse blank samples, and state its potential impact on study results.

For these reasons, there is considerable commercial effort to reduce the absorptive nature of materials used in HPLC systems, particularly within autosamplers. Improvements include using more inert materials, avoiding contact with the syringe needles, and improving needle or valve washing. The present carryover criteria have all but eliminated the direct injection of matrix in bioanalysis, as this approach often results in the buildup of absorptive components [47].

Carryover forced a revision of earlier guidance that recommended randomizing samples. Randomization could result in low level (24 h) samples immediately following a high level (2 min IV) sample. In this example, the preferred sequence to minimize carryover would be to start assaying the latest time point samples and move to earlier ones.

17.7 DILUTIONS

Guidance does not mandate within study dilution QC samples to be used, provided dilutions are conducted with like matrix and tested within validation. The extent to which study samples are diluted must be tested during validation. Although allowed,

this approach does not check that dilutions were properly done during study sample analysis. A preferable approach is to include dilution QC samples whenever required by study samples.

When drug levels exceed the range of the highest dilution, additional dilution factors can be tested during sample analysis. If dilution is performed with an unlike matrix, QC samples must be diluted in the same manner as the study samples and analyzed with the diluted samples. All diluted QC samples should be created within the assay calibration range.

A few laboratories employ a procedure that measures the same sample at multiple dilutions within the same run. This procedure is more common when drug levels are unknown, high dilutions are needed, and/or curve ranges are limited. While this approach can provide more confidence in assay results by replicate demonstration of parallelism, *a priori* acceptance and reporting rules must be established.

17.8 STABILITY

Procedures must evaluate the stability of analytes during sample collection and handling. Conditions used in stability experiments should reflect situations encountered during actual sample handling, including the collection of plasma from blood. A common test is to process plasma or serum during blood collection as shown below:

- spike fresh blood with analyte(s) at low and high QC concentrations
- incubate at ice, room, and body temperatures (or warm blood to 37°C before room or ice processing)
- harvest plasma after 0, 30, 60, and 120 min of storage using a nonrefrigerated and/or refrigerated centrifuge
- transfer plasma to fresh tubes, and store frozen until analyzed together in a single set.

When analyzed, the compound is considered unstable when the measured concentration is less than 85.0% of the initial concentration. If performed at 37°C, this procedure can also be used to assess blood-to-plasma partitioning, as T0 plasma concentrations different from the nominal blood concentration reflect partitioning. As noted previously, knowing the blood-to-plasma ratio can define the assay matrix. For drugs that are highly partitioned into blood, analyte should be measured in blood and not plasma. Highly unstable compounds or those showing time-dependent blood-to-plasma partitioning will require special attention. Testing blood stability in all species is preferred since blood-to-plasma partitioning can be time and species dependent and enzyme levels vary across species. Blood should be freshly collected to avoid loss of enzyme activity.

Esterase activity in rodents is elevated but reduced in higher animals and man. For prodrug and acyl glucuronide assays, conditions that stabilize mouse or rat blood are generally sufficient for human, dog, or monkey studies. However, it is common to have difficulties if the procedure used to establish stability in humans is assumed to be sufficient for rodents. Likewise, oxidases and other enzymes can show similar species specificity. Thiols that form mixed disulfides can be challenging and require conditions to stabilize their breakdown back to parent drug. Owing to interspecies differences in

enzyme activity, it is preferred to determine stability in all test species at the beginning of method development.

Sensitivity to light is often known or easily tested, and hence, yellow lighting for sample processing and amber containers for storage are commonly required. Chemical and light stability assessments have generally been performed on new drug candidates, so this information should be available.

The effect of different anticoagulants on stability should also be considered. EDTA, a common anticoagulant, can be an effective phosphatase inhibitor. Phosphate ester prodrugs collected in EDTA plasma are stabilized. Heparin does not afford the same protection. Likewise, a drug that is a strong chelator may yield different apparent stability in EDTA than when using a nonchelating anticoagulant. Heparin can afford stability by binding drug while EDTA cannot. The stability in different anticoagulants should not be considered equivalent and must always be tested.

When measuring metabolites, it is essential to use an assay that is specific for the metabolite and to employ proper stabilization of any phase II conjugates or interconverting forms (e.g., lactone $\rightarrow$ acid). Phase II conjugates are common. Fortunately, their physiochemical properties often afford a relatively simple separation. The same is not true for phase I metabolites. It is common to have multiple hydroxylated forms, of which either one or many may maintain activity and be of interest for routine measurement. It is critical that all others (and their phase II conjugates) are separated from the metabolites being measured. During method development, it is helpful to obtain a source of known metabolites and spike them into the matrix. Preliminary stability tests using changes from initial response can guide decisions on what stabilization is needed.

The use of selective inhibitors is preferred since these can be added in limited quantities and can result in minimum change to the matrix. This assumes that the general enzymatic process is understood. For esters and lactones, esterase inhibitors such as diisopropyl fluorophosphates (DFP), phenylmethylsulfonylfluoride (PMSF), and 2-thenoyltrifluoroacetone (TTFA) can be effective. For phosphate esters, EDTA and Halts phosphatase inhibitor are commonly used. For oxidases, antioxidants such as ascorbic acid can be effective. Amides may have sensitivity to esterases, but they can also be hydrolyzed by fatty acid hydrolase or proteases. For peptides or proteins, a general protease inhibitor such as aprotinin is often needed. Since an understanding of its metabolic fate may still be evolving for new chemical entities, some screening of different classes of stabilizers may be needed [51].

Many peptides and proteins show high nonspecific binding, requiring the use of special sample collection tubes such as the NuncTM immunoassay tube. Adsorption losses may be misinterpreted as instability. To minimize losses, testing of containers should be considered. Adsorption losses are common in matrices such as urine and CSF and may be overcome using surfactants (CHAPS, Tween-20, Triton X-100), protein (BSA), or EDTA to minimize surface contact or using additives (organic, acid, or base) to enhance solubility. If samples were collected before a procedure is established, it may be possible to recover the absorbed compound from the collection tube. In other cases, drug is irreversibly bound and cannot be recovered. For urine, generally smaller aliquots, rather than the large primary collection vesicle, are stored. Laboratory tests should determine whether or not additives are needed at the collection site. It is a mistake to not test drug adsorption onto urine or CSF containers before a study is started. The procedure should account for any dilution on addition of a stabilizing

solution. Provided they can be properly aliquoted, concentrated solutions are preferred, as the dilution is limited. If a fixed amount is added to the container, one should test extremes in urine volumes. Although it is better to adjust the aliquot to the weight or volume of the urine collection, this is often impractical in the clinic [52].

Use of a low pH (3–4) acid or buffer (formic and citrate) affords optimum chemical stabilization of esters or lactones. Lowering the pH is also important to avoid migration or anomerization of acyl glucuronides [53]. Direct assays for acyl glucuronides must ensure specificity to the 1- β isomer, as one cannot assume that other migrated isomers yield the same MS response. It is therefore important that the 1- β anomer be resolved from all other forms [54]. One should always consider reducing the pH when collecting samples of an acid-containing drug to avoid the breakdown of any potential acyl glucuronides. However, there can be times when the drug itself is less stable under these conditions, so some preliminary stability assessment is warranted before defining sample collection conditions.

When labile ester-containing drugs are measured, both an esterase inhibitor and low pH may be needed. Using a high concentration of acid or buffer alone to denature all enzymes should be avoided. What stabilizes drug and metabolite may destabilize the matrix and complicate the assay. Stabilizers added at high concentration can result in difficulties because of inhomogeneous sampling and poor recovery from a viscous matrix. Hemolysis and gelling are far more common when adding stabilizers. Difficulties in sample collection at clinics may not be predicted from laboratory experimentation. Stabilizers may also cause interference, either directly as chemical interference or indirectly by suppressing ionization (matrix effects).

When adding stabilizers, it is important to correct for any dilution. Stabilizer added to blood within the Vacutainer™ will require an assessment of its partitioning into both blood and plasma. This is generally assumed to be, when corrected for hematocrit, equal. When preparing tubes, it is essential that vacuum is maintained and a regular assessment of the effectiveness of the stabilizer is performed. If plasma or serum harvesting can be done without the need to add stabilizer to blood, then a simpler dilution is possible. In practice, the use of a commercial tube that contains a solid stabilizer (e.g., sodium fluoride) is preferred, as this avoids dilution and preparation issues. While sodium fluoride may afford adequate esterase protection for some drugs in certain species, it may be inadequate for others. This is commonly the case in rodents, so special collection procedures may be needed for rodent studies, whereas a commercially available tube containing sodium fluoride may work for clinical studies.

Once proper means to measure drug levels and stabilize samples have been achieved in method development, validation can proceed. Validation will include appropriate assessments to determine stability. No sample can be reported without ensuring that stability determinations covered the period of sample storage and processing. Stressed (minimum low and high) QC levels must be within 15% of their nominal value. Assessments in the unaltered matrix of qualifying QC samples include

- long-term stability under storage conditions
- freeze–thaw cycles
- bench-top (room temperature and/or ice processing)
- processed sample or extract stability
- reinjection integrity.

Details on the stability procedures are given within the references and are not repeated here. Stability assessments can be an ongoing process as the studies progress. Most laboratories will require a minimum of three freeze–thaw cycles, six or more hours of bench-top stability and extract stability, and two weeks of long-term stability within the validation. If the sample extract is to be reanalyzed, successful reinjection of an acceptable run is required (reinjection integrity). This is different from an extract stability assessment, which is demonstrated using a fresh standard curve.

The stability of reference standards and IS stock solutions must also be demonstrated under storage and bench-top conditions. Secondary stock solutions not immediately used must also be tested. An apparent degradation of more than 10% is unacceptable. Mixtures of stock solutions can be more problematic, as common ion effects may limit solubility. Frozen stock solutions are to be avoided. Testing of different solvents and containers during method development is good insurance that stability assessments in validation will be successful.

17.9 SPECIFICITY AND SELECTIVITY

FDA guidance states that the specificity of the assay methodology should be established using a minimum of six independent sources of the same matrix [9]. This assessment is made by ensuring that background response from six lots of blank matrix is $\leq 20\%$ of the response from the LLOQ sample and $\leq 5\%$ of the IS. Unless a nonselective channel is monitored or analysis at low levels is performed, LC-MS-MS chromatograms generally show few interfering peaks.

FDA guidance recognizes that for MS-based methods, testing six independent matrices for interference may not be definitive [9]. In the case of LC-MS assays, matrix effects should be investigated to ensure that precision, selectivity, and sensitivity will not be compromised. Selectivity is defined within the guidance as “the ability of the bioanalytical method to measure and differentiate the analytes in the presence of components that may be expected to be present.” Guidance also requires that “each blank sample should be tested for interference, and selectivity should be ensured at the lower limit of quantification (LLOQ).” The most definitive test is to measure the LLOQ concentration from six different lots of matrix to $\pm 20\%$ acceptance.

Laboratories need to decide whether a matrix lot that fails can be reanalyzed and how many additional lots should be tested. A reasonable rule would ensure that if more than 10% of tested lots fail, the analyst should consider redeveloping the method. Owing to the specific detection employed in MS, fewer lots of matrix are screened for interference and assessed for selectivity than when using less specific assays such as immunoassay. Accurate quantification may be affected by causes other than nonspecific detection, so measuring QC concentrations in at least six different lots of matrix is required to support assay selectivity.

An assay should be tested whenever clinical studies are performed, when there is the potential for concomitant medication, or when it is used in DDI studies. Over-the-counter (OTC) interference assessments include a mixture of commonly used medications at an appropriately high concentration. For prescribed medications or in DDI studies, tests of the other components are typically done at the anticipated $C_{\max}$ or at a higher value. The potentially interfering drugs and their significant metabolites should be added to the blank matrix and the assay tested to ensure that there is $\leq 20\%$

of LLOQ response and $\leq 5\%$ of IS response. This assessment tests specificity or the direct interference as noted from background response. Infrequently, comedications may cause an indirect effect if they are abundant, may coelute, and are preferentially ionized. Potential interferences in LC-MS are often predictable based on their molecular weight.

Guidance also states that “potential interfering substances in a biological matrix include endogenous matrix components, metabolites, decomposition products, and in the actual study, concomitant medication and other exogenous xenobiotics. If the method is intended to quantify more than one analyte, each analyte should be tested.” Finding a source for these potential interferences can be a challenge. However, the analyst is expected to ensure that every attempt was made to secure and test them. Compounds are added at physiological concentrations to the matrix, fortified with analyte(s), and analyzed. Normal acceptance rules (four of six QC samples must be within 15% or 20% at LLOQ) apply.

The suitability of an assay to measure drug levels in special populations (age/gender, renal/hepatic impaired) should be considered before starting sample analysis. Differences in the clinical chemistry of special populations can impact assay performance. Elevated phospholipids in lipemic populations can cause matrix suppression not apparent in standards prepared from normal plasma. Hemolysis may be more prevalent or extensive, particularly when special processing is required or remote clinics are used. Accumulation of metabolites in slower clearing populations may result in a metabolite interference not previously seen in normal or healthy populations. It is therefore important to have an understanding of the anticipated metabolism before making this assessment. Assay levels may also need to be adjusted to better cover these populations.

Since biotransformation generally involves a change in the molecular weight of the drug, interference from metabolites when measuring parent drug levels is less frequent than when measuring metabolites. Phase II conjugates present concern when coeluting ether glucuronide fragments within the ion source or when acyl glucuronides degrade in-process back to parent drug. Either process results in overestimating parent drug exposure. More common is to have many isomeric or isobaric metabolites, all of which should be resolved from the metabolite being measured. For isomeric metabolites, this generally requires chromatographic separation [55]. For isobaric metabolites, a specific multiple reaction monitoring (MRM) fragmentation is more likely to be achieved. Analysts should take caution in assessing the specificity of a method to measure metabolites. Access to samples from a previous or pilot study helps and should always be considered as a precautionary step. Alternatively, metabolites from *in vitro* sources or animal *in vivo* studies can be spiked into the matrix to assess their potential for interference. Testing from a prior or pilot study is preferred since it affords the best assessment of analytical relevance. The spiking approach, however, should be considered for first-in-human studies.

17.10 CONTAMINATION

In contrast to carryover, contamination is unpredictable and may occur during any part of the study (dosing, sample collection, or analysis). We focus first on sample analysis and later illustrate means to assess study contamination. Contamination may occur in a

limited number of study, standard, or QC samples and to a varying extent. Therefore, assessing its impact can be difficult.

Contamination has become more problematic as instrument sensitivity has increased and samples are processed in closer proximity. For example, a tube-based, HPLC-UV assay that measures microgram per milliliter levels does not present the contamination challenge of a 384-well SPE (solid-phase extraction) LC-MS/MS assay that measures picogram per milliliter levels. Well-to-well or cross-contamination during sample preparation can be reduced by proper programming of the liquid handler method to avoid dripping or tip-to-tip contamination. Disposable pipette tips, although more expensive than fixed tips, can overcome contamination. If fixed tips are needed, appropriate wash steps should be performed. Placement can be considered to minimize its impact; however, isolating high level samples from neighboring wells is impractical.

Other general considerations include separating weighing rooms, where high level stock solutions are prepared, from the LC-MS laboratory. Likewise, bench areas should be covered with disposable paper and instrumentation regularly cleaned to avoid system contamination. Reagent contamination (matrix, solutions), at very low levels, can be difficult to recognize as analyte contamination versus chemical background. An easy test includes adding more MRM transitions so that several profiles are required to have the same relative abundance as analyte. By increasing assay specificity, the analyst can be assured that the problem is contamination and not simply chemical background. For chemical background, an additional transition may serve as the detection channel in a revised method.

If contamination during extraction is suspected, one may use cross-contamination markers to indicate well-to-well contamination during sample processing. Compounds are added in a checkerboard pattern and analyzed to note adjacent well contamination [56]. When used, the analyst must prove that the markers do not influence the assay. The impact must be judged by the bioanalyst using rules defined within an SOP. Options include rejecting the sample(s) or batch, raising the LLOQ, or tolerating the bias (contamination < experimental error).

The bioanalyst has the responsibility to resolve any questions regarding sample analysis. The study director has the responsibility to determine the overall cause(s) for contamination and assess its impact. When needed, the analytical method can also serve to trace contamination within the animal facility or from other sources. Confirmation by reanalysis can generally resolve analytical questions, provided the original sample was not contaminated at first sampling. Given that dosing often occurs at concentrations up to 1,000,000-fold greater than bioanalysis, even a small fraction of dose transferred into or about the tube can find its way inside the sample. For this reason, many laboratories take second samples to avoid random errors associated with sampling contamination.

Following issuance of the EMEA Guideline on Control Animals, more attention was paid to resolving contamination issues [21]. For all pivotal studies that include a toxicokinetic evaluation, control samples should be analyzed. In nonrodent studies, full profiles are required. In rodent studies, sufficient samples about the $T_{\max}$ are needed. When significant contamination is at a level that can impact the validity of the study, the sources of contamination should be investigated. This includes independent analytical and in-life investigations, which are reviewed and reconciled by the study director. It is the responsibility of the study director to assess the significance of impact (greater than no adverse effect level) on the study results. Options to remediate the problem in

future studies should be assessed and implemented. Findings should be stated in the written summaries and highlighted in the nonclinical overview.

When assessing contamination in control animals, the assay range should be considered. To minimize spurious signals being detected as contamination, the LLOQ should be set at an appropriate level. One approach for trough sampling targets an LLOQ that is a percentage of the concentration expected to occur at 24 h after the lowest dose. Interanimal variability must be considered to ensure that the lowest exposed animal within the low dose group can still be measured.

The objective is to determine whether control animals were exposed to drug. Therefore, control samples can be run on a separate plate to minimize the potential of analytical contamination. Contamination sentinels, or additional blanks, can also be used to indicate analytical contamination. An appropriate acceptance rule would require that all contamination blanks included in each analytical run do not yield measurable values. If blanks are below the limit of quantitation (BLQ) and toxicology control samples show quantifiable exposures, control samples can be reassayed in replicate to both confirm analysis and define a reportable value. Confirmation of animal exposure can be accomplished by monitoring for metabolites. For metabolites assayed with parent drug, their ratio should be different from standards or change over time to ensure the lack of sample contamination during analysis.

17.11 SYSTEM SUITABILITY AND RESPONSE CHANGES

Only qualified and properly maintained instruments should be used for drug analysis. To qualify instruments at time of use, a system suitability test may be used. System suitability samples test that the instrument is sufficiently sensitive, selective, and reproducible for the current analytical run. This generally includes replicate testing of the analyte for sensitivity and precision near the LLOQ before starting an analytical run. Similar tests following the run may be used to confirm instrument stability. A mixture of components can test multiple analytes for assay specificity, such as the resolution of critical pairs in a separation. System suitability tests do not replace the required run acceptance criteria. They can be effective in helping to decide whether sample extract can be simply reinjected or a new extraction and reanalysis are needed.

A means to judge individual results, based on the response of ISs, is often dependent on the assay. However, most laboratories have developed general rules that allow *a priori* decisions to reject sample results that show aberrant IS response. The rationale is that any significant change in observed response can reflect an unknown error in sample processing (double spike of IS solution) or an assay change (recovery or matrix effect, injected volume, or instrument response). While an assay may be rugged enough to compensate for an error such as a reduced injection volume, it is sometimes difficult to differentiate an apparent response change from a more fundamental problem. The criterion that only a significant (>50%) change in an individual IS response from the mean IS response is generally used to reject sample results.

Figure 17.1 illustrates an example in which conditioning of the instrument was insufficient before starting an analytical run. This example also illustrates how an individual subject profile may be different from others within the study or QC samples. Today, most laboratories use this type of assessment to help troubleshoot assay runs and make proper decisions on whether samples can be reinjected, reassayed, or not

Figure 17.1 Plot of internal standard response versus injection number illustrates the need for proper conditioning (equilibration) of the LC-MS instrument before starting an analytical run. It also allows assessment of how individual subject data should be treated and when MS sensitivity changes.

reported. Some laboratories include other within-run monitoring such as phospholipid assessments to determine whether ion suppression occurred.

Figure 17.2 illustrates an example where a less potent derivatization reagent was uncovered by monitoring changes in d_3 - Δ^9 -tetrahydrocannabinol IS response. Aged QC samples showed a pronounced difference from fresh standard or QC samples, suggesting either poor IS recovery or less extensive derivatization. When another bottle of derivatization reagent was used with more vigorous vortexing, there was no difference in response between fresh and aged QC samples. The fortunate use of a stable label IS compensated for these changes, as indicated from standard and QC samples. Use of a stable label rather than a structural analog as IS is always preferable, particularly for more complex extractions and derivatizations. Provided the IS is well equilibrated with analyte in the matrix, a stable label will compensate for any subsequent changes. When using stable label ISs, having additional rejection criteria are less critical.

17.12 SAMPLE REANALYSIS

Samples may be reanalyzed for an assignable cause such as a technical error, poor chromatography, unacceptable IS response, or evidence of carryover. The original result is discarded, and the sample is reanalyzed in singlet. The acceptable reanalysis value is reported.

Samples may also be reanalyzed for anomalous results or for PK reasons. These analyses are performed in a manner similar to replicate confirmations of contamination. Typically, confirmatory reanalysis is performed in duplicate. Provided the two replicates agree, a comparison is made between their mean and the original result. Alternatively, the median of the three may be reported. If any one of the three results is below the

Figure 17.2 Plot of d_3 - Δ^9 -tetrahydrocannabinol IS response versus injection number for the analysis of Δ^9 -tetrahydrocannabinol in human plasma illustrates how the extent of derivatization was reduced in aged plasma when using a less potent solution. Fresh reagent and more vigorous vortexing returned IS response of aged to normal plasma (not shown).

LLOQ, the less of the two remaining results is usually reported. When two or more are below the LLOQ, the result is typically BLQ. If only sufficient volume remains for a single determination, a comparison is made between the two results. Either of the three events may occur: the original result is confirmed and reported (<15%), a mean value is reported (15–30%), or no value is reported (>30%). There are several acceptable means to judge replicate repeat analysis. A decision tree, established within an SOP, should define the procedure.

There are a number of situations where the performance of QC samples may not adequately mimic that of study samples from dosed subjects (incurred samples). Reasons for the difference can be considerable, including metabolites converting to parent drug, protein-binding differences in patient samples, recovery issues, sample inhomogeneity, matrix effects and interference from formulation, or drug-modulated differences in clinical chemistry. These factors can affect the reproducibility and accuracy of the concentration determined in incurred samples. Since accuracy is difficult to determine in a study sample, replicate analysis (interassay precision) is used as a surrogate for accuracy. Irreproducibility, therefore, exposes inaccuracies, which warrant further investigation. While the causes for irreproducibility are often characterized and minimized during method development, it is important to assure that the assay is under control when the method is applied [57]. For this reason, more recent studies have required the assessment of ISR. An underlying objective is to determine whether and why the variance noted from incurred samples differs from QC samples.

Within GLP toxicology studies, a proper evaluation of ISR and accuracy needs to be performed once on each species used in toxicology studies. Consistency of the animal's genetics and environment makes it unnecessary for additional incurred sample investigations to be performed once the initial assessment has been performed. The chance of incurred sample variability is far greater in humans. Therefore, randomly

selected subjects should include a minimum of 10% of total analyzed samples. For larger studies, 5% of total sample size is allowed. Samples must be analyzed within the period of stability [12,13].

In both GLP and clinical studies, the difference between the initial and reanalyzed values should be $\leq 20\%$ (small molecules) in at least 67% of reassayed samples. Unlike repeat analysis for anomalous results or for PK reasons, ISR is performed in singlet from selected samples about the $C_{\max}$ and in the elimination phase. It is recommended that the selected samples be representative of each study period and dose cohort. Initially, this was recommended to be referenced to the original result, assuming that it was more likely the correct value. The proper approach is to reference to the mean value:

$$\% \text{Variability} = \frac{\text{Repeat} - \text{Original}}{\text{Mean}} \times 100$$

Reference to the mean produces a consistent assessment, regardless of the order by which the two results were obtained [13]. For this reason, LIMS software, such as Watson, support either calculation.

When the criteria cannot be met, an investigation to understand the assignable cause of the irreproducibility is warranted. This will proceed from several probable causes to one assignable cause [58]. The simplest cause may be an assignable execution error, which may isolate the failure to that day's run. More complex reasons may implicate other reasons (Table 17.3). Once defined and corrected, a decision regarding reporting of data can be made. Study sample analysis cannot be accepted until the investigation is complete, documented, and appropriate follow-up actions are in place. In case of an unassignable cause, all ISR samples can be reanalyzed, along with additional samples, in two or more different batches. Results of all relevant batches should be evaluated to obtain interday ISR data. No assignable cause can require the redevelopment/validation and reanalysis of all subject samples.

TABLE 17.3 Assay Issues and Probable Causes for ISR Failures

Issue	Causes
Improper processing of study samples	Execution error (dilution, IS spiking) not seen in QC samples
Lack of rugged method	Assay not optimized and variance in study samples greater than that in QC samples
Interference from isomeric or isobaric metabolites	Metabolic specificity not fully tested
Metabolites $\rightarrow$ parent	Improper stabilization procedure
Rate of interconversion affected by the law of mass action	Interconverting forms not tested at same ratio as in study samples
Subject differences in protein binding	Extraction process not rugged
Differential recovery	Time-dependent recovery observed in study samples but not QC samples
Sample nonhomogeneity	Sampling error (improper thaw/vortex)
Endogenous interference and matrix effects	Error in defining matrix variability across populations because of insufficient lot screening

Investigation of ISR failures may implicate results, runs, studies, or assays. Understanding the cause will determine its impact and the direction taken. A unique sample may not have a reportable value. A unique population may present problems for the assay, failing study results and requiring revision/revalidation of a new assay. If the assay is implicated, it can invalidate results from other studies in which the assay was used. It is therefore critical to thoroughly test assays before use and ensure proper training of staff.

ISR results may be documented in the final bioanalytical or clinical study report and/or as an addendum to the method validation report. In selecting samples to be reanalyzed, a variety of concentrations, time points, and patient populations should be chosen, depending on the drug and its DMPK (drug metabolism and pharmacokinetic) properties. This can be a challenge when the analyst has limited information. First-in-human, proof-of-concept, special population, and bioequivalence studies are examples of studies that must include incurred sample concentration verification. Most perform ISR within all clinical studies. Study sample results obtained for establishing ISR may be used for comparison purposes and are generally not used in calculating reported sample concentrations.

To properly handle failed ISR runs, the laboratory must have an SOP on how to conduct and document investigations. The principal investigator should lead the analytical investigation and report their findings to the study director or the individual who monitors the overall conduct of the study, quality assurance, and management. Probable causes are reduced to definitive cause(s) through a series of hypothesis testing. The investigation report is issued with the study report in which the problem is described, reanalysis results are defined, and an assignable cause is identified. The identified cause serves to define preventative and corrective actions to avoid future errors.

Ruggedness testing during method development and validation can serve to reduce ISR failures. Robustness assessed by tracking assay performance across different analysts, laboratories, and studies can be invaluable in defining trends and causes for failures [59]. A critical question is to determine why there was an analytical error not uncovered by normal standard and QC acceptance criteria. Some assay-related causes of ISR failures are shown in Table 17.3. It is expected that ISR failures be fully investigated to an assignable cause and corrected, in a manner similar to assessing manufacturing failures when out-of-specification results are seen. It should be considered that imprecise assays may, on occasion, fail ISR in the same statistical manner in which one set of QC samples fail, while others pass acceptance criteria. The analyst should work to ensure that the assay can be executed more precisely before undertaking a larger ISR sampling.

17.13 MULTIPLE ANALYTE ASSAYS

It is becoming more common to expect that LC-MS assays perform multiple analyte assessments within a single run [27,48]. Cassette dosing and metabonomics are the extreme examples [60,61]. Within regulated bioanalysis, this is desired for antiviral indications where comedication drug therapy (highly active antiretroviral therapy (HAART)) is needed to overcome drug resistance. In many areas, the desire to measure parent drug and its metabolites drives multiplexed assays.

Simultaneously measuring multiple analytes increases the statistical probability of run failures. Results should not be rejected for the remaining analytes if one analyte fails. Concentrations from the first accepted run should be reported. If this analyte is repeated in simultaneous assays when analyzing for different analytes, it is not necessary to quantitate the already reported analytes. All results should be maintained and available for review.

17.13.1 Drug Metabolites

It is common to have metabolite exposures at significantly different levels than the parent drug, particularly in early clinical studies where metabolite levels are unknown. On repeat analysis of diluted ALQ parent samples, a second reportable value for the metabolite is often obtained. Source data from all acceptable runs, regardless of whether the concentrations were reported, should be retained.

MIST guidance requires one to demonstrate steady-state exposure in at least one toxicology species for all major (>10% of parent AUC) circulating human metabolites. Traditionally, this has been assessed by single dose ADME studies using radiolabeled drug. Studies such as these can be difficult and expensive to perform early in drug development. It is worth noting that the requirement to demonstrate exposure at steady state has made multiple tracer (100 nCi) dosing using AMS a viable option. Regulatory expectations are that these assessments will be completed after proof-of-concept trials but before launching larger clinical trials. This affords some time to assess steady-state exposures and nonradiolabeled approaches such as using tiered assays.

For extensively metabolized drug candidates, measuring large numbers of metabolites at steady state may be better achieved using tracer dose AMS studies. If one chooses to measure metabolites using LC-MS assays, tiered assays afford a means to make more informed decisions. In comparison to a traditional ADME study (50 μ Ci dose, liquid scintillation counting), multiple LC-MS assays defer synthesis of GMP (good manufacturing practice)-grade radiolabel, tissue distribution, dosimetry estimates, and the cost of a clinical ADME study. Savings by attrition of compounds that do not meet proof of concept is significant. In contrast to doing nothing until a late clinical ADME study is performed, the tiered assay approach avoids surprises and focuses resources on unanticipated, unique, or disproportionate metabolites.

Without reference standards, UV and MS responses are sometimes used as an estimate of parent drug and metabolite levels. UV response is often more consistent, particularly when its chromophore is unaffected by metabolism. MS ionization and MS/MS fragmentation have considerable variability for structurally similar (and dissimilar) metabolites. One should not assume that UV or MS response will be comparable. Assessment at high levels from *in vitro* sources can afford more security in these estimates. Relative response factors of the metabolite to parent drug are determined and used to calibrate MS response for lower level determinations. Comparisons of this type should be considered as first-tier assays.

Another approach compares response ratios across species. This assumes similar stability, recovery, matrix effects, and response proportionality in all species or minimizes them by dilution into human plasma. Interspecies differences in enzyme levels, protein binding, and phospholipid levels suggest that analyte stability, recovery, and matrix effects may vary across species. Mixing animal samples with an equal amount of human plasma compensates for these differences and has been shown to be a good procedure

by which simple response ratios afford safety margin estimates [62]. Response proportionality by testing study samples at multiple dilutions (parallelism) is also required. If studies were performed at different times and samples stored for different periods of time, long-term stability is still in question. Reanalysis of aged study samples may be used to support long-term stability. However, reference of stability to initial response rather than its nominal concentration may mask instability, as the breakdown product of one metabolite may fortify an unstable analyte. Ratio comparisons across species should be regarded as second-tier assays.

Third-tier assays generally employ calibrators that have been qualified with some limited assessment of stability. One approach previously mentioned uses metabolites from radiolabeled animal or human *in vitro* studies spiked into human plasma as standards for quantification [31]. To ensure accurate quantification, the radiolabeled profile must separate all metabolites from each other. Metabolite radioactivity is referenced to parent, which has been measured using LC-MS. Resulting curve ranges, therefore, reflect the original proportions within the spiked radiolabeled sample. Dilution in matrix affords the standard curve. The advantage of this approach is that steady-state assessments across species can be made quickly without the need to isolate or synthesize metabolites. Human metabolites that are disproportionate are readily noted. Those metabolites that are insignificant or for which there is adequate safety coverage may need little further investigation. It should be noted that similar approaches are possible using nonradiometric detection, provided response is specific only to metabolites and proportional to their concentration. Unfortunately, inductively coupled plasma-mass spectrometry (ICP-MS), chemical reaction interface for mass spectrometry (CRIMS) and N or S-chemiluminescence detection suffer from either high background in biological matrices or an inability to detect low background elements such as fluorine [63–65]. This approach, however, requires that the metabolite is observed in animals or in human *in vitro* sources.

A second, more time-consuming approach involves isolation of individual metabolites before NMR identification and quantification [29,30]. This approach is closer to the traditional method of isolating metabolites, synthesizing them, and assessing their purity. The difference is that the metabolite isolated from biological sources need not achieve a level of purity expected by synthesis. Only microgram levels are needed, and although the isolated metabolite should be the major component, it need not be high in purity. As NMR response is independent of structure, accurate quantification is achieved by direct measurement of a metabolite resonance using a parent peak for calibration. In contrast, synthetic reference standards are generally qualified by difference, subtracting impurity identified in their preparation.

Since cross-species comparisons reference human-to-animal exposure, the exact assessment of purity is not critical. That said, the direct determination is likely more accurate when the compound cannot be either synthesized or isolated in high purity. Limited supplies will make it difficult to characterize impurities, so a direct measurement will be more accurate. Likewise, the inclusion of a reference standard provides much greater accuracy than just measuring response. Furthermore, the direct measurement approach using NMR should provide both the confidence needed for structural integrity and purity assessment for its use in a regulatory assay.

In combination with strategies for biologically sourcing metabolites and qualifying them without a certificate of analysis, tiered assays can provide a reasonable estimate of steady-state exposures. Samples should be stored at -70°C and analyzed as soon as

received. Whether this is achieved using single or multiple assays is dependent on the extent and diversity of metabolism, required sensitivity and dynamic ranges, and risks one is willing to take by trying to achieve too much within a single assay. Analysts and development teams should consider whether a metabolite is worthy of GLP bioanalysis at its present stage of drug development or whether a tiered approach would be better.

Human metabolites for which there is abundant safety coverage are of less concern and support a tiered determination. The MIST guidance should not replace structure–reactivity assessments. Metabolites not expected to be active or reactive, such as sulfate or ether glucuronides, pose less concern [66]. Alternatively, low levels of highly reactive metabolites may not be seen in plasma, as they do not escape the liver in significant abundance. Accurate measurement of a trapped metabolite or both precursor and product metabolites in plasma may be required. Each metabolite should be considered on a case-as-case basis. Having an accurate assessment is critical when metabolism-mediated toxicity is observed [67].

Once the human metabolism is known, a solid decision can be made regarding what assay(s) would be effective in supporting clinical drug development. To allow proper assessment of PK–PD, parent and significant human metabolites should be measured to regulatory standards. It may be worthwhile to include abundant metabolites into this assay, particularly if they are active, potentially toxic (structural alerts), or implicated in drug clearance. Decisions regarding assays for toxicology studies in animals include safety concerns in humans.

17.13.2 Drug Interaction Studies

DDI is a major reason for toxicity, particularly when new drugs are used in larger, more diverse populations. New chemical entities often clear the body as metabolites or through transporters, both of which are subject to inhibition or induction by other drugs or their metabolites. In addition, the presence of genetic polymorphism and disease as well as age- or gender-related differences in enzyme or transporter function can serve to reduce the normal safety margin. The previous FDA Guidance on DDI studies has focused on *in vitro*–*in vivo* correlations, providing guidance on what studies are needed in clinical drug development [68,69]. More recent publications have addressed both CYP-mediated and transporter-mediated drug interactions [70,71].

When desired, it is possible to perform a more general screening of new drug candidates using a cocktail of marketed drugs that serve as cytochrome P450 probe substrates. As many as 10 analytes (parent and metabolite for 5 probe substrates) are measured in this coadministration study. Common substrates in DDI cocktails include warfarin (2C9), dextromethorphan (2D6), omeprazole (2C19), midazolam (3A4), and caffeine (1A2, NAT-2, XO). Other combinations have used debrisoquin (2D6), (*S*)-mephenytoin (2C19), chlorzoxazone (2E1), caffeine (1A2), and dapsone (3A4). Flurbiprofen has been added to cover 2C9. Other cocktails include mixtures of preferred probe substrates that assess clinical relevance to the drug under development [72,73]. This approach could find more utility, provided a common set of probe substrates and metabolites were used. Mixing of probe substrates and metabolites requires more extensive assay development and validation for each DDI study.

Measuring a metabolite that is specific to one biotransformation pathway provides a more powerful assessment of a drug interaction than just measuring a change in parent drug exposure. Unfortunately, the interaction of large and small molecules is

less predictable than small-molecule interactions. Small-molecule interactions mostly occur as a result of liver enzyme or transporter inhibition and are well predicted from *in vitro* studies. Large–small molecule interaction can be target-related and noted from enhanced or reduced pharmacological effect [74]. Regardless, most drug development programs now include an assessment of the effects of biologics on the systemic levels of small-molecule drugs.

17.14 ASSAY TRANSFERS AND CHANGES

There can be multiple opportunities to transfer assays. Each of these affords a chance to improve an assay. Assay transfer within a laboratory or across laboratories involves an assessment of its equivalence following the change. Depending on the nature of the change, this may involve either a partial or full validation. Transfers do not require cross-validation or conformance testing. However, testing at least QC samples from the other laboratories may expose a bias. Inclusion of incurred samples may expose issues not seen using just QC samples. Laboratories need to demonstrate ISR many times within clinical development, so requiring a similar test at assay transfer would be a wise investment. Cross-validation using incurred samples is only required when two different assays are used within the same study. However, at New Drug Application (NDA) filing, an assessment of exposures across populations is made, so assays are expected to give equivalent results in all studies.

At the discovery-to-GLP transfer, one should take every opportunity to learn from discovery studies. MS optimization should test ionization, instrument tuning, sensitivity, and assay range. Often, a generic extraction and fast gradient separation suitable for discovery needs revision to meet regulatory expectations. Automated screening of LLE (liquid–liquid extraction) or SPE procedures can test diverse conditions for high recovery and minimum matrix effects [75]. Mobile phase and LC column screening should test gradient or isocratic conditions using various mobile phases and columns. Attention to the separation of any interference, carryover, peak shape, and MS sensitivity should be made. MS sensitivity is affected by the separation for several reasons. ESI is concentration dependent, and mass flux to the source is impacted by peak shape and resolution. Efficient drying of ESI droplets is aided by reducing surface tension, so better response is achieved when using a higher percentage of organic in the mobile phase. Having the right pH or ionizing agent (e.g., ammonium) is also critical to ionization. For absorptive compounds, through-column recovery may be low. While calibrators may compensate for reduced LC recovery, the net effect is poorer sensitivity. It is also common to substitute a better, more abundant analog or preferably stable label IS at this phase of method development.

At the IND toxicology-to-clinical phase, assay sensitivity and a wide dynamic range are critical as one prepares for SAD (single ascending dose) and MAD studies in man. Achieving a high sensitivity assay may require larger volumes and the use of a more selective extraction or exploring alternative ionization or derivatization approaches. The addition of active metabolites to better assess PK–PD is a common change. At this time, it is unwise to include too many metabolites until samples from the top dose of the MAD study are profiled. Profiling and tiered assays can provide estimates as to whether these metabolites are unique or disproportionate and therefore require

long-term monitoring using a regulated assay. This approach will minimize changes to the clinical assay throughout drug development. As discussed previously, a human urine assay is generally needed.

When moving further to proof of concept, assays in other fluids or tissues may be needed to demonstrate penetration to the site of action or toxicity. Site-of-action questions will generally require analysis only in human and the pharmacology species. Toxicity questions will include human and the most sensitive safety species. In many cases, a representative human sample is unavailable. For human lung, bronchoalveolar lavage and macrophage exposure can serve as its surrogate. Some virology indications are supported by showing penetration into PBMCs. This is particularly important when drug is known to be actively transported or limited by intracellular metabolism. There is limited guidance on the extent of validation required for a penetration study. If limited to a single matrix and critical to explaining efficacy or toxicity, a full validation including stability assessments should be considered. For tissues, stability assessments may be limited to homogenates. This is generally sufficient for toxicology studies, as drug safety sites often can perform homogenization before freezing tissue samples.

Whenever assays are transferred across different companies, such as when a pharmaceutical company transfers an assay to a contract research organization, there is risk that any change could impact assay performance. The dilemma is whether one should allow changes to better optimize an assay or stay with the present assay. The transfer of knowledge and good communication are critical. Assessments of accuracy, precision, and failure rates provide metrics on its success. To confirm a lack of bias, the exchange and analysis of both QC and incurred samples can demonstrate equivalence before starting a new study. If additional tests are required beyond what is normally covered by the SOP, preparing and executing a validation plan is essential.

17.15 DOCUMENTATION

When preparing analytical and validation reports, a summary table of all analytical runs should list runs with run identification, dates of analysis, whether runs passed or failed, reasons for any failures, and, for analytical runs, any deviations from the validated method. QC data from validation runs that only failed to meet QC acceptance criteria with no assignable cause for failure should be included in the precision and accuracy estimation. Deviations from SOPs and assay procedures and significant unexpected events should be identified and their impact assessed. This includes any defined outliers [12]. For those performing large numbers of studies, having a LIMS is a critical component to ensure consistency in documentation and to manage the time associated with these tasks.

Source data documentation should include the conditions of use. For instance, stability determinations during method validation should record experimental conditions such as storage temperature and duration. Materials should be traceable to source and date of collection. Modification of calibration response and QC levels should be documented with sufficient detail to demonstrate that the changes were justified or followed established procedures. For chromatographic methods, source documentation should include original and reintegrated chromatograms for accepted runs, along with the reason for changing integration parameters across a run or for individual samples within a run. Electronic audit trails that record changes to integration parameters must be enabled [12].

A total of 5% of all chromatograms from randomly selected subjects, including QC samples and standards, must be submitted with an NDA and/or ANDA (Abbreviated New Drug Application). For bioequivalence studies, 20% of chromatograms from serially selected subjects are submitted.

Final reports for either validation or study sample analysis must include a complete account of the performance of the method. This includes a tabular listing of the actual QC results from all runs during method validation and accepted runs during study sample analysis. A table listing reassayed samples, reason for reanalysis, and values for the original, reassay, and final reportable result should be included in the final report.

Drug concentration data from the rejected runs need not be included in the final report; however, a brief description of the reasons and a tabular listing of rejected runs should be provided. Compliance has the added value that thorough documentation at the end of each study makes work easy when the common technical document (CTD) is assembled.

17.16 INSTRUMENT QUALIFICATION

Qualification of instrumentation and computer validation are beyond the scope of this chapter. Suffice it to say that the proper installation and operational and performance qualification of all instrumentation are required before performing regulated bioanalysis [76–79]. This responsibility is shared among the vendor, analysts, and informatics organizations. Testing and validation of functionality unique to your laboratory requirements will not have been performed by the vendor and therefore must be done. Design qualifications tend to be the domain of the vendor, although this aspect can be assessed during the vendor audit and at the time of instrument selection. User specifications and a validation plan should be developed. From vendor assessments, system functionality can be verified and any gaps identified. Consider customization when configuring and testing options. UAT should include a traceability matrix to regulations. Failures in executing UAT scripts are categorized as to their severity and decisions made for any procedural or software changes. Results and all reports must be thoroughly reviewed before the production release memo is issued. SOPs, postproduction, validation review, change management, disaster recovery, deviation, and exception documentation are required.

17.17 EXPLORATORY CLINICAL STUDIES

Many organizations have sufficient discovery or preclinical resources and confidence in animal studies that would predict success in the clinic. Demonstrating proper exposure at a therapeutic dose or target engagement in the clinic is expected for IND candidates. When unsure of success, eIND studies allow the assessment of new chemical entities that have undergone limited safety testing [80]. Subtherapeutic doses or microdoses afford the opportunity to determine ADME properties using AMS or target engagement using a positron emission tomography (PET) ligand [81]. A microdose is defined as <1/100th of the dose of a test substance calculated (based on animal data) to yield a pharmacologic effect of the test substance with a maximum dose of $\leq 100 \mu\text{g}$.

For some, the eIND presents a fast-to-fail decision. There is always the concern that DMPK properties at very low doses are not reflective of therapeutic doses because of dissolution rate-limited absorption or saturation of clearance [82]. Having clarity on the biopharmaceutics is therefore fundamental to understanding whether one or several new chemical entities are good candidates for microdosing. Not having a good *in vitro*–*in vivo* correlation and poor allometric scaling of the PK in animal species could be justification.

If microdose PK is the only desired endpoint, cold dosing of microgram quantities in humans and LC-MS measurements of picogram per milliliter concentrations in plasma are alternative means to estimate human exposures [83]. In a preclinical test, proportionality for several drugs in rats was considered as validation of a general methodology to support microdosing in humans [84]. Sprague-Dawley rats were given oral doses of 0.167, 1.67, 16.7, 167, or 1670 mg/kg. LC-MS provided sufficient sensitivity to study the PK of antipyrine, carbamazepine, atenolol, and digoxin, but not metoprolol. Dose proportionality was achieved between a microdose and up to 1000-fold higher doses for antipyrine, carbamazepine, and digoxin. State-of-the-art MS (API 5000) instrumentation was required. There was limited sample cleanup and no derivatization. The LLOQs ranged from 5 to 20 pg/mL. This illustrates the potential to quickly adapt existing LC-MS assays to an eIND study. Others have followed with examples of the potential of microdosing to obtain an early assessment of ADME properties [85].

High sample enrichment and derivatization may be needed to achieve microdosing objectives. For some small molecules and most peptides, immunoprecipitation can be used to enrich a larger volume of sample before analysis [86]. If the capture antibody from an enzyme-linked immunosorbent assay (ELISA) is used, the resulting LC-MS assay will share its epitope specificity. More details are presented later in the analysis of larger molecules. Molecularly imprinted polymers, sometimes referred to as *plastic antibodies*, are an alternate means to enrich samples [87]. They are more readily produced than antibodies but have considerable limitations. Derivatization generally employs means to make molecules more thermally stable or readily ionized in APCI or by attaching ionized surfactants in ESI [88,89]. In either approach, one should test derivatization conditions to ensure that they are robust and carried to completion. Limiting reagents or conditions can generate differences across samples.

17.18 LARGER MOLECULES

Peptides, small proteins, and oligonucleotides are representative of mid-size molecules (1–10 kDa) that can be directly measured using LC-MS to low nanomolar or sub-nanomolar levels. Van den Broek [90] has reviewed the use of LC-MS methodology to perform quantitative bioanalysis of peptides in biological fluids. Noted are the common requirements to add displacement reagents (similar peptides) or other proteins (serum albumin) to compete with binding sites and to add acid, solvents, or surfactants to overcome nonspecific binding. Immunodepletion of most abundant plasma proteins is also mentioned as a means to enrich samples. If time allows, developing an antibody to immunocapture the desired peptide would be preferred. In an example of derivatization, an octyl quaternary ammonium group was added to enhance ESI properties [89]. The addition of both a charged and hydrophobic group by derivatization aids

by enhancing its surface properties and ion yield. Reporting of both extraction and recovery through immunoprecipitation and derivatization from the low and high QC samples in the validation would be expected. Yields should be sufficiently high in both processes so as to avoid assay variability.

The analysis of insulin using LC-MS illustrates its value both as a biomarker and, when dosed, for its PK [91]. Radioimmunoassays (RIAs) and ELISA of insulin often are nonspecific across higher species, making it difficult to separate endogenous animal insulin from dosed human insulin in toxicology studies. Dosing of human insulin reduces endogenous animal insulin, so measuring a composite profile with a nonspecific RIA is problematic. Predose and insulin precursor C-peptide levels can be determined, but a more direct measurement with a specific assay affords one the chance to measure both drug levels and the effect.

While peptides may have picomolar potency and may require high sensitivity assays in clinical studies, toxicology studies may be supported using far simpler LC-MS assays. Hu and Kamberi [92] reported the analysis of apolipoprotein A-1 mimetic peptide D-4F in rabbit plasma from 0.02 to 40 µg/mL. When using a mixture of LC-MS and immunoassays in toxicology and clinical studies, one should have a clear understanding of assay differences to assess safety margins. The same can be said of discovery-to-preclinical bioanalysis when assessing the minimum effective dose. Assay bias should be assessed to ensure adequate safety margins and human dose selection.

Cross-validation of ligand-binding and LC-MS assays using both QC and study samples can help to illustrate bias. Although this is not required within the guidance, it should be considered when making assessments in large molecules. Larger molecules have tertiary and quaternary structures that may be critical to ligand-binding assays but unrecognized by LC-MS. If required for potency, immunoassay could be the better choice. Likewise, differences in specificity may be exposed when comparing assays. LC-MS requires extraction, so total drug is measured, whereas some immunoassays measure only free drug levels. Differences can be considerable.

Plotting study sample results for an immunoassay on one axis and LC-MS results on another should yield a correlation. There are no *a priori* acceptance criteria. The ideal correlation is a 45° line (slope = 1) that would indicate perfect agreement between the assays. The best fitting line will display the actual relationship. A comparison of precision between the assays can be done by computing the standard deviation of replicate results for each sample. Comparison of individual and grand means can be done using analysis of variance.

Therapeutic oligonucleotides have been under development for two decades [93]. Oligonucleotides are a special challenge and present their own stability and sensitivity problems. Hybridization-based ELISA methods generally afford the required speed and sensitivity for these potent drugs. Identification of individual metabolites, including those generated from 3'- or 5'-exo/endonucleases, is generally not possible using ELISA. While LC-MS may afford a more direct means to determine the metabolism of oligonucleotides, ionization efficiency in negative ESI is often limited and variable [94]. Matching chromatographic separations to MS detection is also a challenge. Reducing and controlling the formation of salt adducts through addition of bases such as triethylamine are critical to successful analysis. At best, low nanomolar concentrations have been measured [95]. Besides the parent drug, the 3'N-1, 5'N-1, 5'N-2, and 5'N-3 metabolites were also capable of being measured in rat plasma.

These types of separations require system suitability samples to be analyzed both before and after runs to ensure that separation of any critical pairs and MS sensitivity have been maintained. It is also important to understand the activity of any metabolite. Any multiplexed assay for oligonucleotides should be based on a strategy that is similar to small-molecule drug metabolites. Significant circulating active metabolites in humans should be included with the parent assay to assess PK–PD. Hopefully, this can be achieved within a single assay. It may be impossible to source others, so a tiered strategy may be needed. Particular attention to off-target toxicity is needed, as the similarity of oligonucleotide metabolites to parent drug may force one to consider regulatory assays for all metabolites.

Differences between present acceptance rules (15/20% for small vs 20/25% for large) have resulted in some confusion when mid-size molecules are measured. For instance, when oligonucleotides or peptides are measured using LC-MS, should acceptance criteria be tighter than when measured using immunoassay? As peptides and oligonucleotides are typically manufactured without heterogeneity, tighter standards may be applied. However, both an ELISA and an immunocapture LC-MS assay may share a reagent expressed with high variability (e.g., polyclonal antibody). A reasonable approach might be to target $\pm 15\%$ but to allow the acceptance criteria to be adjusted up to $\pm 20\%$, contingent on the accuracy and precision noted within the validation.

New approaches to deliver drugs, such as ADCs, are good examples of where the released peptide drug measured using LC-MS may be measured to the same rules as its parent biologic. In many cases, the parent ADC is measured using ELISA and results would be accepted with an accuracy and precision of 20% (25% at LLOQ). However, one could equally make the case that a small peptide measured by LC-MS as a protein surrogate should be determined to small-molecule rules (15% accuracy and precision, except 20% at LLOQ).

Moving to larger molecules (biologics) requires careful consideration of whether a highly specific LC-MS assay is useful. If ELISA measures all active components, a functional assay should be the primary measurement. What role does a peptide-as-protein surrogate assay then play in drug development? When high affinity antibodies are difficult to obtain, there may be good reason for LC-MS detection. Its higher specificity can compensate for a less selective capture reagent.

Proteins are not generally directly amenable to LC-MS bioanalysis. This is particularly true for proteins that have undergone extensive posttranslational glycosylation or to which polyethylene glycol (PEG) has been added. Proteins, following their isolation can be reduced in size using proteolysis and measured by LC-MS. Tenecteplase (MW 58,777 Da) has been determined in rat plasma in the range of 5–125 $\mu\text{g/mL}$ [96]. Plasma samples were reduced using dithiothreitol and reacted with iodoacetamide before overnight trypsin digestion. LC-MS analysis of three tryptic peptides served as surrogate for the protein drug. This relatively simple procedure afforded sufficient sensitivity to determine the PK in rat. While the LLOQ of the ELISA was much lower, this approach will be of increasing use to speed early drug development.

The LC-MS approach is time consuming but can provide detailed information of amino acid changes that are unrecognized by an immunoassay. For instance, one can interrogate whether a specific Asn residue has been hydrolyzed to Asp and measure its amount in plasma. This is a common degradation of peptide drugs, including insulin. Rearrangement can also occur during this process, which would require chromatographic separation. The LC-MS assay could provide complementary information on

impurities, degradants, and metabolites that cannot be determined using an immunoassay.

Enfuvirtide (MW 4492 Da) and its deamidated metabolite M-20 were determined in human plasma [97]. The assay range for parent drug was 10–2000 ng/mL, while that for M-20 was 10–500 ng/mL. A deuterated stable label was added as IS before protein precipitation. The resulting supernatant was directly analyzed using LC-MS. The same drug and its M-20 metabolite were measured in a similar assay [98]. Deuterated stable label IS was added before chymotrypsin digestion. LC-MS analysis of four smaller peptides was shown over the 100–10,000 ng/mL range. Since the peptide drug was of sufficiently low molecular weight, either a direct or indirect analysis under low resolution MS/MS conditions afforded an accurate measurement of the separated drug and M-20 metabolite. The easier method would avoid proteolysis; however, this assay was an order of magnitude less sensitive.

Blending of exposure data across studies and species from multiple LC-MS and ligand-binding assays will be of increasing importance in the drug development of peptides, oligonucleotides, and protein therapeutics. It will be critical to demonstrate adequate analytical figures of merit for stability, recovery, matrix effects, and specificity. A fundamental understanding of the differences in these assays through appropriate cross-validation must also be obtained.

17.19 DRIED BLOOD SPOTS

DBSs have been infrequently used for many years in the field of bioanalysis. Over the past four years, there has been considerable interest, largely driven by Glaxo Smith Kline, in the use of DBSs instead of plasma [99,100]. There are numerous advantages, particularly from the *in-life* portion of the study. For rodent studies, less blood (15 μ L) is required, which reduces the numbers of animals. Toxicology of satellite animal groups can be eliminated. Repetitive sampling from the same mouse also reduces interanimal variability in PK studies. In the clinic, labor-intensive plasma harvesting is eliminated. Needlestick bleeds replace indwelling catheters. Likewise, the need to store and ship samples at reduced temperatures is eliminated. The overall effect is to reduce errors at remote clinics, allowing higher quality from global studies.

The challenge becomes one for the bioanalyst. The analyte must be well recovered from filter paper without the introduction of matrix effects. As only a fraction of the total blood spot is used, the punch sampling must be sufficiently large to ensure the required LLOQ. Reemergence of DBSs has been aided by the improved performance of LC-MS systems. Owing to their sensitivity requirements, highly potent drugs may not be amenable to DBSs. However, there are a considerable number of drugs that require no greater than low nanogram per milliliter detection sensitivity, a target achievable for many DBS applications. High affinity enrichment and smaller-volume analysis including the use of capillary LC-MS may assist in obtaining additional detection sensitivity. Sampling across the blood spot must be consistent to ensure a reproducible sample since aliquoting a precisely measured volume at collection is not done. At present, automation is limited. There is considerable effort by automation companies to provide more innovative, off-the-shelf solutions in the near future.

As more investigators explore the potential of DBSs in clinical studies, there will undoubtedly be regulatory bioanalytical guidance that comes forth in the general area

of microsampling. Many are performing qualifying studies in which blood, plasma, and DBSs together are sampled and analyzed. When corrected for hematocrit and blood–plasma partitioning, the PK would be expected to be equivalent. This type of test is likely needed to bridge data for a new chemical entity that is moving through drug development.

17.20 CONCLUSIONS

The nature of regulated bioanalysis is ever changing. New methodology, technology, and novel drug candidates challenge past practices. Best policies from GMP and GCP (good clinical practice) are being incorporated into GLP. Most notable has been the use of ISR to confirm or refute original results and the use of out-of-specification procedures to investigate the causes of failed runs [101]. Although this has placed additional costs on the industry, it has greatly improved the quality of bioanalytical data. No longer does the first reportable result go unchallenged.

As a result of the Third Crystal City Bioanalytical Workshop, common procedures were adopted for validation and sample analysis of both large and small molecules, regardless of the analytical technology. These changes in regulated bioanalysis were greatly needed to assist in measuring more complex drug candidates. Products made by synthetic routes are integrated with those from biological sources, including modified peptides, proteins, and antibodies. LC-MS and ligand-binding assays share drug development roles, defining PK–PD and assessing drug safety. As such, it is likely that future guidance may also better integrate biomarker assays into regulated bioanalysis.

Global drug development has brought forward new cultures and perspectives into our science. Adaptive clinical trial design put more emphasis on bioanalysis to escalate doses and biomarker assays to define proof of concept. The next generation of regulated bioanalysis will see new challenges from evolving science and technology that will further shape work practices and standards.
